ABSTRACT

Intracranial hypertension refractory to maximal medical treatment is a nightmare for both neurointensivists and neurosurgeons caring for patients with severe traumatic brain injury (TBI). Decompressive craniectomy represents one of the most powerful weapons to potentially interrupt deleterious cerebral events responsible for secondary brain damage and death after TBI. Neuromonitoring tools, such as cerebral microdialysis, may contribute to understanding the pathomechanisms of acute brain injury, provide an early warning of secondary cerebral deterioration, and help in selecting the patients most suitable to benefit from this very invasive surgical rescue therapy. Furthermore, neuromonitoring can be used as a measure of the effect of decompressive craniectomy on neurochemistry derangement and brain energy crisis jeopardizing the injured brain. In this chapter, we discuss experimental and human data on the role of brain metabolism monitoring to detect the effect of decompressive craniectomy on brain energy metabolism after severe TBI.

Keywords: decompressive craniectomy, intracranial hypertension, cerebral microdialysis, neurobiochemistry, energy metabolism

INTRODUCTION

Traumatic brain injury (TBI) has the capacity to transform human life more than almost any other event, and brain herniation, due to an intracranial mass lesion or edema, is the most dramatic and feared sequela of TBI. Occasionally, even mild or moderate TBI can result in death, or persistent vegetative state due to herniation. Intracranial pressure (ICP) monitoring, and the therapies that comprise neurocritical care are directed primarily at preventing herniation and the less dramatic forms of secondary brain damage after TBI. Decompressive craniectomy (DC), the focus of this book, is emerging as one of the most potent, though highly invasive, forms of therapy to prevent secondary brain damage and herniation, but has not yet been accepted as “the standard of care” by many experts in the field. Of the many therapeutic maneuvers available after severe TBI, DC may be the most controversial. DC as a treatment of intracranial hypertension refractory to conventional treatments represents a challenge, for both the neurosurgeon and the neurointensivist, owing to the controversies regarding optimal patient selection, timing, and perioperative management. The purpose of this chapter is to briefly review some of the most important mechanisms of secondary brain damage after severe TBI, and discuss how DC may ameliorate these. We review the limited human data available demonstrating how DC influences or mitigates these damage mechanisms. Clearly much more mechanistic research, in both animal TBI models and the injured human brain in the neurosurgical intensive care unit, is needed to open new avenues of therapy for the future.

NEUROBIOCHEMISTRY IN SEVERE TBI

Various factors, such as injury severity, presenting Glasgow Coma Scale (GCS) score, age, early hypoxia, and hypotension are the most important prognostic markers after severe TBI [1]. While the primary insult cannot be prevented except by “social engineering and environmental modifications,” secondary insults and resuscitation are the major targets of therapeutic intervention [2]. Well understood is the fact that both ischemic and non-ischemic metabolic disturbances lead to ongoing insult in the injured brain, which is far more vulnerable than in normal parenchyma because of impaired cerebrovascular autoregulation, metabolic impairment, and release of numerous harmful cellular mediators. New robust mechanisms that are capable of harming the injured brain after TBI are discovered every year, and the possibility of discovering new therapeutics for TBI such as small molecule drugs, monoclonal antibodies, and gene therapies is the major impetus for TBI research. However, before these mechanisms can be accepted, they should be validated in the injured human brain after TBI.

A few methods exist to evaluate this in the living brain, such as MRI, MR spectroscopy, *in vivo* microdialysis, and *ex vivo* analysis of cerebrospinal fluid and blood biomarkers.

Microdialysis

Intracerebral microdialysis is one such technique that detects ongoing biochemical changes at bedside in near real time. Depending on the availability of an appropriate

analytical assay, virtually any soluble molecule in the interstitial fluid can be measured by microdialysis. A perfusate solution that does not contain the analyte of interest is passed through a microdialysis probe inserted into the relevant area. These probes have a semipermeable membrane, through which diffusion of the analyte occurs along a concentration gradient. These molecules are then recovered and analyzed. We must understand that the measured values for interstitial products using microdialysis vary with perfusion rates since that affects the relative recovery of the molecule. Normative data for microdialysis are dependent on several technical factors, including the perfusion rate, microdialysis membrane, and duration of perfusion. With reduction in the perfusion rate to 0.3 $\mu\text{L}/\text{minute}$, the *in vivo* recovery increases. Reinstrup et al. have defined the reference baseline values at 0.3 $\mu\text{L}/\text{minute}$. The common variables studied include glucose, lactate, pyruvate, glutamate, and glycerol [3].

Most commonly, microdialysis catheter probes (molecular weight cutoff of 20 kDa, 10-mm membrane) are placed in the perilesional tissue. The probes are perfused with CNS perfusion fluid at 0.3 $\mu\text{L}/\text{minute}$ and samples collected for intracerebral glycerol and lactate/pyruvate (L/P) ratio every hour. Concentrations of glucose, lactate, pyruvate, glutamate, and glycerol in the microdialysate are analyzed using the microdialysis analyzer. Data that can be recorded at each hour for each individual include hourly microdialysis values, in addition to such neurophysiological parameters as ICP, cerebral perfusion pressure (CPP), mean arterial pressure (MAP), and plasma glucose (see Figure 1).

Under normal aerobic conditions, glucose is converted to pyruvate by glycolysis and taken up in the citric acid cycle and the mitochondrial respiratory chain. In TBI, shear forces and the release of free radicals and intracellular calcium lead to inactivation of mitochondrial respiration and the stages of the Krebs cycle. Conversion of pyruvate to large amounts of lactate occurs as a result of anaerobic metabolism. The use of microdialysis in severe TBI has primarily been used to evaluate small molecule fluxes that are the manifestation of this “energy crisis,” including the delivery of glucose and its conversion to pyruvate by glycolysis. Normally, the pyruvate would then be used in the tricarboxylic acid (Krebs) cycle. As one of many manifestations of this mitochondrial dysfunction, pyruvate is metabolized to lactate by anaerobic metabolism (Figure 2). Mitochondrial swelling is easily seen, by electron microscopy, from the injured human brain, and is the structural correlate of these metabolic derangements (Figure 3). The L/P ratio is therefore used as a marker of anaerobic metabolism and has been well correlated with dynamic measurements of impaired aerobic metabolism on positron emission tomography scanning after human TBI [4-7].

Glutamate is another small molecule easily measured by microdialysis that may be used as a marker of excitotoxicity, and has been seen to be elevated 100- to 200-fold in severe primary human TBI, and in very severe secondary insults; it is correlated with herniation, hypoxia/ischemia, and poor outcome [4, 8, 9].

Glycerol is a less widely reported, but well validated marker of free radical generation, bimolecular leaflet cell membrane damage, phospholipid breakdown, and consequent free fatty acid release. This results from hypoxic/ischemic events, as well as calcium release into neurons and astrocytes, via the inactivation of protective enzymes such as peroxidase and superoxide dismutase, among others [4, 10-12].

During this TBI-induced mitochondrial dysfunction, the biochemical pattern is characterized by an elevated L/P ratio (L/P ratio >25) with a pronounced increase in lactate concentration at a normal or increased pyruvate level, also known as type II elevation of the

L/P ratio. This pattern contrasts with the condition during “pure” cerebral ischemia (e.g., stroke) where the pyruvate level is very low (pyruvate <70), known as type I elevation of the L/P ratio [13-16].

Figure 1. Clockwise from left: ICU pilot software showing time traces of two analytes, lactate/pyruvate ratio, lactate and pyruvate; microvials with collected cerebral dialysate; perfusion fluid attached to the microcatheter; insertion of microdialysis catheter at the time of decompressive craniectomy.

Figure 2. Glycolytic pathway: generation of lactate occurs during anaerobic metabolism.

RATIONALE OF MONITORING NEUROCHEMISTRY AND BRAIN OXYGEN DELIVERY IN PATIENTS WHO MAY REQUIRE DC

Maintenance of adequate cerebral tissue oxygenation is a primary goal in the care of neurological critically ill patients. Because brain ischemia and hypoxia are central causes of brain damage, prompt detection and correction of any event jeopardizing oxygen supply and utilization is fundamental in neurocritical care [17]. In particular, TBI is a dynamic and heterogeneous disease in which the activation and interaction of multiple pathophysiological cascades, such as neuroinflammation, oxidative stress, excitotoxic damage, mitochondrial dysfunction, and cerebral blood flow alterations, contribute to brain damage and to worsened neurological outcome. Furthermore, several potentially brain damaging events, known as secondary insults (e.g., hypotension, hypoxia, high ICP, low CPP, hyperthermia, and seizures, among others) may occur after TBI and contribute to worsened neurological outcome depending on the severity, duration, and number of insults [18]. Therefore, the prevention of secondary brain injury is recognized as a cornerstone in the treatment of severe TBI and has improved neurological outcomes over decades. Because of the complexity of these secondary neurochemical events after severe TBI and the inability to detect them by imaging, neuromonitoring techniques have been advocated and attempted in patients in the neurointensive care unit.

In this complex scenario, the use of neuromonitoring tools may provide clinicians with essential information that could be helpful to optimize clinical decision making. Various monitoring techniques each offer a slightly different perspective on brain pathophysiology. For example, cerebral metabolism, oxygenation, electrophysiology by electroencephalography and electrocorticography and blood flow and neurochemistry by microdialysis have been evaluated together and separately in TBI patients, and there is a growing belief that such “multimodal monitoring” may provide a more accurate overall picture.

Figure 3A. Massive intra-operative brain swelling with hyperemia and “metabolic crisis” leading to herniation.

Figure 3B. Electron microscopy to demonstrate swollen mitochondria 30 minutes after severe TBI.

Figure 4. Over 5 days of intracerebral microdialysis (MD) monitoring, the good Glasgow Outcome Scale (GOS) outcome group showed a rising cerebral glucose and cerebral glucose/blood glucose (RBS) ratios.

Some of these new cerebral monitoring techniques have corroborated the existence of mechanisms of potential damage after TBI, such as mitochondrial failure, spreading depolarizations, non-convulsive seizures, glutamate excitotoxicity, and low brain oxygen tension. However, questions remain. Can these techniques guide therapy in the ICU, as ICP monitoring has done historically? Can detection of these events before a rise in ICP be used to focus a “targeted therapy,” thus preventing high ICP and, potentially, reducing the need for DC? If clinically applicable, this could be a true “holy grail” for neurocritical care.

The TBI literature reports DC cases where the decision has been guided by neuromonitoring after TBI [19-24], subarachnoid hemorrhage [25-27], meningitis [28], and large middle cerebral artery infarcts [29, 30].

In this complex arena, monitoring neurochemistry and brain oxygen delivery by microdialysis and brain tissue oxygenation techniques can possibly provide clinicians with additional information in several related aspects of management. Robust neurochemical changes and alteration in brain tissue oxygenation have been detected in response to clinical pathophysiological events after an acute brain injury, so that the specific effect of DC on the different pathomechanisms of injury can be difficult to isolate from primary injury and other therapies using these neuromonitoring tools. Below, we review the studies supporting the hypothesis that neuromonitoring can provide additional information regarding the effects of DC on neurochemistry.

RESULTS FROM PRECLINICAL STUDIES

Whether DC may interrupt the vicious circle of events responsible for failure of brain energy metabolism and cellular damage caused by refractory intracranial hypertension has been debated. Nevertheless, in the more homogeneous and controlled condition represented by experimental animal models of acute brain injury, researchers have tried to answer several issues concerning the role of DC in this setting.

One study investigated the neuroprotective effect of DC on lateral controlled cortical impact in rat models at 3 hours, 1, 2, 3, and 7 days after TBI. Using magnetic resonance imaging and concomitant proton magnetic resonance spectroscopy to characterize the metabolic response after acute brain injury, the authors found that DC could reduce brain edema [31]. In particular, they observed that animals undergoing DC exhibited reduced apparent diffusion coefficient (a marker of brain edema severity), reduced contusion volume, decreased lactate/creatinine ratio, and higher N-acetylaspartate/creatinine and choline/creatinine ratios versus animals without DC. Decreasing N-acetylaspartate (a marker of mitochondrial damage), increased lactate (a marker of hypoxia), and decreased choline (a marker of membrane breakdown) were all observed and support a neuroprotective role for DC in experimental models of cortical impact injury. Furthermore, the demonstrated beneficial effects and improved mitochondrial dysfunction after DC were sustained up to 7 days after injury [31].

Another study investigating the role of DC on brain edema formation after lateral fluid percussion injury in rats found that at 48 hours after TBI, aquaporin-4 expression in the animals with DC was significantly decreased compared with the animals without DC, as an expression of a reduction of cerebral edema formation [32]. Other authors had previously

evaluated the hemodynamic and metabolic effects of experimental DC, using positron emission tomography in the early phase after experimental DC in the normal brain tissue in cats. Schaller et al. demonstrated that cerebral blood flow was significantly decreased and the oxygen extraction ratio significantly increased after DC, and that in regions with the most severe cerebral blood flow reduction, metabolism was also reduced [33].

Furthermore, using beta amyloid precursor protein and neurofilament-200 as histopathological markers of axonal injury, Friess et al. saw reduced pericontusional axonal injury at 7 days post injury [34]. This interesting finding suggests that DC in this animal model may actually reverse axonal destruction due to traumatic or diffuse axonal injury induced by the impact. Moreover, after controlled cortical impact in mice, early craniectomy was able to prevent secondary brain damage as shown by a more than 50% decrease in the amount of brain edema formation and no lesion expansion in craniectomized mice within the first 24 hours after trauma [35]. More recently, in a model of controlled cortical impact in mice, to test the hypothesis that reduction in ICP induced by DC would result in decreased axonal injury and white matter atrophy, investigators found that closed cranial animals (those that underwent replacement of the previously removed bone flap) had increased white matter atrophy, with smaller corpus callosum and external capsule volumes than did open cranial animals (bone left out) [34].

CLINICAL MICRODIALYSIS AS A TOOL TO UNDERSTAND THE EFFECTS OF DC

Neuromonitoring can be a measure of the effect of treatment (i.e., DC) on cerebral ischemia and hypoxia, as it relates to neurologic outcomes. The results of neuromonitoring can offer clinicians a perspective on the appropriate time-window for the investigated rescue treatment [34-36].

Guidance of critical care management after DC, especially in those cases characterized by occurrence of a hyperemic response after the procedure, may be an important next step. In fact, postoperative derangement in cerebrovascular pressure reactivity may be present after DC and could cause malignant cerebral hyperemia, as may be seen in the operating room (Figure 3A) in the case of very high CPP [37]. Failure of restoration of brain energy metabolism resulting from a persistent energy metabolic crisis may occur, demonstrated by mitochondrial dysfunction or signs of cerebral ischemia, and clearly needs further evaluation [37].

Overall, the evaluation of the effects of DC on neurochemistry and brain oxygen delivery may contribute to a better understanding of the role of this procedure in the treatment of intracranial hypertension.

Gupta et al. [24, 38] studied a cohort of 41 patients with severe TBI undergoing DC. The group had a mean age of 33.42 years (standard deviation [SD] 13.55), range 18–85. The median post-resuscitation GCS score for the study group was 7 (range 4–7). Twenty-six patients (63.4%) had a favorable outcome (Glasgow Outcome Scale score 4 or 5) and 15 patients (36.6%) had an unfavorable outcome (Glasgow Outcome Scale score 1–3) at 6 months' follow-up. See Table 1.

All patients were managed in the neurointensive care unit with multimodality monitoring over a course of 5 days following DC. A total of 3813 hours of monitoring values of various microdialysis variables were obtained. There were no episodes of catheter insertion-induced hematoma or meningitis.

Table 1. Demographics of patients who underwent DC [38]

	Total	Good Glasgow Outcome Scale score	Bad Glasgow Outcome Scale score	P
N	41	26 (63.4%)	15 (36.6%)	
Mean age (standard deviation), years	33.41 (13.55)	36.40 (17.5)	31.54 (10.85)	0.28
Median Glasgow Coma Scale score	7	7	5	0.12

BIOCHEMICAL MEASUREMENTS

In our series of 41 cases, 25 in the original publication and 16 we have added since then for continued monitoring, we made the following observations regarding various biochemical parameters [24, 38].

Glucose

There was no significant difference in mean random blood sugar (RBS) ($P = 0.166$) (7.26 mmol/L versus 7.61 mmol/L) and mean cerebral glucose ($P = 0.221$) (1.84 mmol/L versus 1.95 mmol/L) values among the good or bad outcome groups, respectively. A poor correlation between plasma and cerebral glucose for the entire cohort (Pearson's correlation coefficient 0.01 with $P = 0.642$) was noted. This suggests that brain microdialysis glucose values are not always reflective of changes in systemic glucose. A significant difference was noted in the incidence of hyperglycemia (RBS >10 mmol/L) and hypoglycemia (RBS <5 mmol/L) between the two groups ($P < 0.0001$). The microdialysis glucose values during the episodes of hyperglycemia or hypoglycemia did not show a significant difference between the two groups ($P = 0.86$ and $P = 0.46$). However, we noticed that microdialysis glucose values showed a rising trend over the course of 5 days of monitoring in the good outcome group. Similarly, the good outcome group showed rising microdialysis glucose to blood glucose ratios. This indicates a recovering metabolic state in the brain tissue that may indicate a good outcome [24, 38].

We noted that the difference between the two groups, comparing episodes of cerebral hypoglycemia during systemic hypoglycemic episodes (RBS <5 mmol/L) was significant ($P = 0.0026$). This probably reflects increased susceptibility of brain tissue to hypoglycemia, related to impaired autoregulation, in the poorer outcome group. The previous assumption that cerebral extracellular glucose concentration would change in parallel with blood glucose values may be an oversimplification [39]. An increased metabolism of intracerebral glucose may lead to lower microdialysis glucose values following head injury [40]. Similarly, poor correlation has been noted between blood and extracellular brain glucose in patient with

subarachnoid hemorrhage [41]. Abate and colleagues attributed poor control of microdialysis glucose based on blood glucose values secondary to the metabolic heterogeneity that may be expected in TBI patients [42]. In our study, we also found poor correlation between microdialysis glucose and blood glucose values ($R^2 = 0.01$, $P = 0.64$) [38].

Lactate/Pyruvate Ratio

The mean L/P ratio was significantly higher in the poor outcome group than the good outcome group (mean 80.2 [SD 320.3] versus 45.8 [SD 169.8], $P < 0.01$). CPP had an inverse correlation to the L/P ratio for the whole cohort as would be expected with increased perfusion ($R^2 = 0.04$, $P = 0.03$). An inverse correlation was also seen in the unfavorable outcome group ($R^2 = 0.14$, $P < 0.01$). Taking both L/P ratio < 45 and CPP 70 mm Hg together as cutoffs, we found a statistical significance in predicting outcome ($P = 0.03$).

Nikaina et al. showed that CPP and L/P ratio have significant effects on the long-term outcome prognosis after a spontaneous cerebral hematoma [43]. They proposed a cutoff CPP of ≥ 75 mm Hg and L/P ratio ≤ 36 . Parafarou et al. suggested a CPP cutoff > 75 mm Hg, L/P ratio < 37 , and glycerol < 72 micromoles/L as markers of good outcome [44]. Our study shows somewhat similar results (L/P ratio < 45 and CPP ≥ 70 mm Hg).

In the event of TBI, ischemia and decreased cerebral blood flow can occur even with CPP ≈ 65 –75 mm Hg [45]. Therefore, CPP alone is not a reliable indicator to assess adequacy of the cerebral blood flow in such patients. There is, however, no consensus for the ideal CPP values in severe TBI. Some authors have warned about a higher risk of acute respiratory distress syndrome with a CPP above 70 mm Hg, with no additional benefit to outcome [18]. A lower CPP goal of 60 mm Hg has been endorsed by the American Association of Neurological Surgeons, and recently the Brain Trauma Foundation suggested a general threshold in the area of 50–70 mm Hg [46]. An elevated L/P ratio can have various causes such as ischemia, hyperglycolysis, and mitochondrial dysfunction [6, 47, 48]. The key to finding the appropriate cutoff for CPP may depend on keeping a favorable metabolic profile, as indicated by low L/P ratios.

Glutamate

Increased levels of extracellular glutamate have been reported in human TBI, with persistent glutamate elevation seen in the post-injury period. In ischemic models, levels have been seen to rise from 2 $\mu\text{mol/L}$ to > 20 $\mu\text{mol/L}$. In our study, levels of glutamate were significantly higher in the bad outcome group than the good outcome group: 40.31 $\mu\text{mol/L}$ (SD 67.24) versus 21.68 $\mu\text{mol/L}$ (SD 38.31), $P < 0.01$ [24]. Recovering trends of glutamate values were seen in the good outcome group over a period of 5 days, consistent with our previous studies [15]. This suggests that glutamate could be a useful prognostic marker in TBI.

Mitochondrial Dysfunction and Ischemia

Brain Trauma Foundation guidelines recommend a target CPP value between 60 and 70 mm Hg to avoid ischemia for survival and favorable outcomes; however, attempts to maintain CPP >70 mm Hg with fluids and pressors should be avoided because of the risk of acute respiratory distress syndrome. As mentioned earlier, the L/P ratio elevation has been seen to occur in conditions of ischemia (with a fall in pyruvate) and also in mitochondrial dysfunction (with a near normal pyruvate level). Gupta et al. noted the unfavorable outcome group showed significantly higher episodes of both mitochondrial dysfunction and ischemia than the favorable GOS group: 65.9% versus 55.9% ($P < 0.0001$) and 13.9% versus 7.24% ($P < 0.001$), respectively [24, 38]. These changes were more pronounced with pericontusional catheter placement. We compared the results for the time spent in each category, post-resuscitation GCS and age to the Glasgow Outcome Scale score at last follow-up (GOS 1-5). For most patients being monitored for a period of 3 to 5 days, this meant that even a 10% increase in ischemia (8-10 hours) as shown by microdialysis, doubled their odds of progressing to a worse outcome group. Similarly, for mitochondrial dysfunction, the odds ratio was 1.475 (95% confidence interval: 1.066–2.040) ($P = 0.019$). During episodes of ischemia, the ICP was significantly higher and the CPP significantly lower [48]. In view of the odds of worsening outcome with each episode of ischemia, close control of CPP should be maintained.

Ischemia and mitochondrial dysfunction require different therapies. If a condition is characterized as ischemic based on microdialysis values of the L/P ratio and pyruvate levels, therapy is indicated to increase CPP or to pharmacologically improve microcirculation. On the other hand, bedside detection of non-ischemic mitochondrial dysfunction should lead to consideration of novel therapies targeting mitochondrial function, such as hyperbaric oxygen [48].

LITERATURE REVIEW

A recently held consensus meeting by the International Microdialysis Forum, led by P. J. Hutchinson, combined literature review with expert opinion to produce practical guidance for the use of cerebral microdialysis (see Table 2) [49]. The authors noted that the correlation between cerebral and serum glucose was weak; however, the trend of values for cerebral hypoglycemia, L/P ratio, and CPP correlated well with outcomes in the majority of cases of severe TBI [26].

CONCLUSION

Scholars have compared the complexity of the brain and its cellular function and arrangements to the cosmos, and TBI has been termed the most complex disease, affecting the most complex structure known to man. With advancements in technology, pre-hospital care, resuscitation and targeted management in a dedicated neurointensive care unit, the prognosis has improved for severe TBI from ~80% mortality in the 1950s to ~20% in the current

decade, with well-resourced neurosurgical intensive care units and dedicated care teams [50]. In the future, new monitoring techniques and therapies will make DC a crude, obsolete, archaeological relic, but our challenge is to use the methods available now to better understand the events that make DC necessary, and to prevent worse secondary disability, after TBI. Although cerebral microdialysis and other types of multimodal monitoring have been in use for almost two decades, their potential is huge for the future.

Table 2. Summary of the consensus statements and recommendations regarding cerebral microdialysis

	Consensus Statement 2015	Recommendation	Evidence
Methodology of microdialysis	20 kDa catheters for small molecules and 100 kDa for large molecules.	Flow rate of 0.3 μ L/min with hourly sampling recommended.	
Reference values	Glucose (Tier 1 intervention)	<0.2 mmol/L <0.8 mmol/L	Low glucose associated with poor outcome.
	L/P ratio (Tier 1 intervention)	>40 >25	High L/P ratio associated with poor outcome.
	Lactate	>4 mmol/L	L/P ratio better than lactate
	Glutamate (Tier 2)	Raised in ischemia	May be useful in prognostication.
	Glycerol (Tier 3)	Limited specificity	No definitive evidence.
Management guidelines	Glucose	Raise RBS if low. Treat perfusion, if low CPP.	
	L/P ratio	If ischemia, raise CPP. If low PbtO ₂ , improve oxygenation.	
Catheter placement	Focal injury	Ipsilateral In normal brain	Multiple catheters may be used.
	Diffuse injury	Right frontal lobe	
Monitoring	Trend is more important than absolute point values.

Robert Horry, retired basketball player

ABSTRACT

Intracranial hypertension (ICHTN) can result from several medical conditions, including metabolic syndromes, brain tumors, ischemic or hemorrhagic strokes, or traumatic brain injury. The importance of ICHTN and raised intracranial pressure (ICP), put simply, relates to the blood's inability to perfuse the brain adequately. This, in turn, is ultimately responsible for impaired neurologic function resulting from homeostatic changes affecting ICP, cerebral perfusion pressure (CPP), mean arterial pressure (MAP), and metabolic state. Medical optimization of neurologic function and outcome through careful observation of the patient in an intensive care unit and use of neurologic vital signs such as ICP, CPP, MAP, pressure reactivity index, and mixed venous oxygen saturation has made some progress in recent years, yet certain patients remain with intractable ICHTN. For these patients who fail an established stepwise medical escalation in care, decompressive craniectomy is often the only option to lower ICP.

Keywords: intracranial hypertension, cerebral perfusion pressure, intracranial pressure, traumatic brain injury, edema

INTRODUCTION

For a meaningful discussion and ultimately a critically defensible treatment protocol for intracranial hypertension (ICHTN), we first need to define ICHTN. Over the years ICHTN has usually meant an intracranial pressure (ICP) greater than 20 mm Hg in the setting of some clinically relevant disease state. For example, in a healthy person a simple Valsalva maneuver can transiently raise ICP above that threshold, but it rapidly returns to baseline without obvious consequence. However, following a traumatic brain injury (TBI), for example, several now classic studies have shown that patient outcomes are better in those patients who had ICP controllable to less than 20 mm Hg [1-3]. A slightly higher threshold of 22 mm Hg was found in a larger retrospective cohort study by Sorrentino [4]. It is important to note that herniation can occur below this threshold and often depends on lesion location in TBI [5]. Also cerebral perfusion pressure (CPP) by definition is affected by ICP, i.e., $CPP = \text{mean arterial pressure (MAP)} - \text{ICP}$, and, and goals for optimal CPP have also been established. Yet even this straightforward number may have to be tailored to the individual patient's needs depending on the presence of intact cerebral autoregulation [6].

All of these numbers, these neurologic vital signs, help guide therapy for the brain-injured patient, especially in the deeply comatose patient where that may be all we have, but for all other patients any definition of ICHTN must include the medical first principle of 'how is the patient doing?' Close observation for changes in neurologic exam along with radiographic imaging has proved to be perhaps as powerful a tool as ICP monitoring [7]. Thus as care is delivered to improve numbers, it is important to remember that each patient may ultimately have a unique set of optimal parameters that leads to the best outcome.

CAUSES OF INTRACRANIAL HYPERTENSION

From the microscopic to the macroscopic, raised ICP can result from several causes, and can lead to life-threatening underperfusion of the brain or even herniation. Macroscopically, ICHTN generally results from three broad mechanisms—either trapped cerebral spinal fluid (CSF; hydrocephalus), mass lesion (tumor or blood), or brain swelling. Although medical management certainly plays a role in patients with hydrocephalus and mass lesions, a majority of this chapter will deal with the medical management of patients with ICHTN predominately driven by brain swelling. Although discussed in greater detail in other chapters of this volume, a brief review of microscopic processes leading to brain swelling, such as vasogenic edema, is necessary to understand current medical treatment modalities.

Normally, ICP is between 10 and 15 mm Hg, fluctuating with the cardiac and respiratory cycles. As mentioned, transient spikes may occur with Valsalva maneuvers such as coughing, but a sustained pressure above 20 mm Hg is generally accepted as a reason to intervene [8]. Macroscopically, ICP is driven by the Monro-Kellie doctrine relating to the fixed volume of the cranial vault, and the contents of blood, brain tissue, and CSF that occupy that space. Under normal circumstances the volume of these compartments is tightly regulated, and perturbation in one compartment can lead to a compensatory response in another; for example, brain swelling can lead to displacement of CSF to the spine. However, the capacity

to buffer large changes in intracranial volumes is limited, and soon small incremental changes in volume lead to exponential changes in ICP.

Multiple primary injuries can lead to raised ICP, and these primary injuries may lead to a complex array of secondary injuries. For example, TBI may result in an acute subdural hematoma, brain contusion, seizure, and hypoxemia as primary insults leading to both generalized and focal increases in ICP through mechanical and secondary swelling through cytotoxic and vasogenic edema. Each of these insults as well as the secondary injuries may have an idealized treatment algorithm, thus contributing to potential complexity. Stepwise escalation of medical intervention leading ultimately to decompressive craniectomy (DC), if all else fails, has become standard of care. However, it is worth discussing each cause of ICHTN to perhaps parse out areas for further inquiry.

ETIOLOGIES AND TREATMENT OF INTRACRANIAL HYPERTENSION

Traumatic Brain Injury

TBI is perhaps the best-studied cause of increased ICP, and this has resulted in a fairly protocolized treatment algorithm. Yet outcomes over the past few decades have not improved much, indicating the need for more work to be done. TBI is the leading cause of death and disability between the ages of 1 and 44 years old. TBI represents a substantial health burden, and in the United States alone over 1.7 million new cases are diagnosed each year, contributing to 50% of trauma deaths (braintrauma.org). In emerging economies the increased use of motor vehicles supports a rise in young male TBI [9], and in more mature states TBI from falls in an aging population has countered a fall in motor vehicle-related TBI owing to seatbelts and speed limits [10].

Trauma has the potential to set in motion the most complex causes of raised ICP. Mass lesions including subdural hematoma, epidural hematoma, intraventricular hematoma, and contusion can all increase intracranial volume, thus leading to increased ICP. Significant focal lesions can be managed surgically, but of particular concern is expansion of hemorrhagic contusions. Indeed, some preclinical and clinical data suggest that DC itself may contribute to hemorrhagic progression of contusion through a proposed release of an initial tamponade [11, 12]. And even without DC, some studies show up to 50% of hemorrhagic contusions can progress over the acute period, thus affecting focal if not global ICP [13]. Altered coagulation, as determined by partial thromboplastin time (PTT), prothrombin time (PT), and platelet number, may play a role in the severity of progression, yet in roughly 50% of hemorrhagic progression of contusion, this is not the case, implicating alternative mechanisms of capillary breakdown separate from the primary injury [13]. Preclinical studies by Simard et al. [14] suggest a novel mechanism whereby trauma causes the upregulation and expression of the Sur1-Trpm4 ion channel in the brain that then acts as an end executioner to kill capillary endothelial cells, causing fragmentation and contusion expansion. Interestingly, the Sur1-Trpm4 ion channel can be blocked by low amounts of the sulfonylurea glibenclamide to prevent hemorrhage expansion in animal models and thus may one day be of use following TBI (see Chapter 1).

Brain swelling and cerebral edema following TBI is the most serious challenge to managing ICP, and is thought to contribute to over 50% of TBI mortality [15]. In order to treat cerebral edema and brain swelling, first we need to understand some basic concepts and mechanisms of cerebral edema. Cerebral edema itself is a pathological process involving increased fluid and water mass contained in the brain interstitial space. Thus various components of brain swelling and cerebral edema that have been classically defined, including cytotoxic edema, ionic edema, and vasogenic edema, refer to different processes and indeed perhaps different stages of this pathological state. Cytotoxic edema can be thought of more as a premorbid state since cytotoxic toxic edema does not lead to brain tissue swelling but merely the swelling of brain cells whether that be neurons, support cells, or endothelial cells [16]. Ionic edema and vasogenic edema are two processes that involve transvascular flow of ions, water, and proteinaceous material. Cytotoxic edema is the influx of osmolytes into cells, particularly astrocytes, often in a damage-control response to injury or toxins. Cellular influx of osmolytes is often due to primary active transport or secondary transport. Primary transport is ATP dependent, while secondary transport relies on already established gradients. A common mechanism in astrocytes relies on collapse of the extracellular Na^+ gradient following injury, with Cl^- and water following secondarily. Triggers for this process include altered K^+ , low pH, and high glutamate concentration [17]. Transmembrane flow of water can be by diffusion, co-transport, or channels such as aquaporin-4. Cytotoxic edema generates a gradient between the brain interstitial fluid and the vascular fluid. Thus the next phase of brain swelling, ionic edema, constitutes transport of ions and eventually water to follow across the endothelial membranes on the luminal side as well as the abdominal side to the brain interstitial fluid. This is an ionic process the next phase of which depends to a large degree on blood brain barrier breakdown to allow large macromolecules to flow from the vascular department into the interstitial fluid, thus constituting vasogenic edema. It is important to note that during the cytotoxic edema and ionic edema phases, only ion gradients contribute to brain swelling, but during vasogenic edema both ionic *and* hydrostatic forces are at work. Thus one can predict during the vasogenic stages of cerebral edema that it is possible to actually exacerbate edema by driving the mean arterial pressure too high. In preclinical and clinical studies, the Sur1-Trpm4 ion channel has been shown to play a central role in cytotoxic edema and vasogenic edema and may constitute an important therapeutic target in future trials (see Chapter 1).

ICP monitoring of the severely brain-injured patient has become customary in the modern intensive care unit (ICU). Perhaps surprisingly, the data to support this practice come mostly from observational studies, and this has led to a standard of care based on the fact that significantly raised ICP is associated with poorer outcomes [1-3]. Thus the current Brain Trauma Foundation (BTF) guidelines have softened the recommendation for monitoring in severe TBI patients to simply “reduce in-hospital and 2 week post injury mortality” [8]. What remains to be determined is exactly what patient population needs to be monitored, for how long, and in what manner. Prior BTF guidelines suggested that TBI patients with a post-resuscitated Glasgow Coma Scale (GCS) of 3–8 and abnormal computed tomography (CT), or normal CT and age >40 years, or abnormal posturing, or systolic blood pressure (SBP) <90 mm Hg should have an ICP monitor. A good quality randomized controlled trial (RCT) conducted in Bolivia and Ecuador by Chesnut et al. [7] showed no difference between patients having an ICP monitor and those managed by clinical exam and radiographic

findings. Various lower quality studies have been conducted that show increased mortality with monitoring [18], no difference [19-21], or improved outcomes [22-24].

Studies have compared management based on ICP versus CPP, and tried to determine an optimal CPP. If one assumes in the most basic sense that the greater the CPP is, then perhaps the better the outcome will be, as long as cerebral autoregulation is intact and CPP is within the autoregulatory window. However, studies have found conflicting minimum values for CPP, either 60 mm Hg or 70 mm Hg, and thus the current BTF recommendation is for between 60 and 70 mm Hg, with pressure above 70 mm Hg possibly leading to pulmonary failure [4, 25, 26]. When ICP optimization was compared to CPP management, Huang et al. [27] found a lower favorable outcome in the ICP than the CPP targeted group ($P < 0.04$). The optimal CPP may rely on intact cerebral autoregulation with a better tolerance for a higher CPP as compared to those with disrupted autoregulation who are more appropriately managed by ICP control [28].

To help find an optimal CPP, the cerebral pressure reactivity index (PRx) can be determined. In the normal range of intact autoregulation, blood pressure and ICP are negatively correlated. That is, an increase in cerebral blood flow is followed by cerebral vasoconstriction that decreases the volume of the intracranial blood compartment, thereby decreasing the ICP. With the PRx, clinicians can identify the individualized blood pressure range in which autoregulation is intact, thereby preserving CPP [29]. The individual patient's optimal CPP (CPPopt) is the CPP at which the PRx is most negative, that is, when autoregulation is most appropriately responsive. Aries et al. [30] showed in a large retrospective cohort of severe TBI patients requiring neurocritical care that 6-month Glasgow Outcome Scores (GOS) were better in patients whose CPP was maintained within 5 mm Hg of their CPPopt. Mortality was greatly increased in patients whose CPP was more than 5 mm Hg below their CPPopt [30]. Drawbacks include the need for the specialized software ICM+ (University of Cambridge) to calculate the Pearson correlation coefficient between mean ICP and mean BP, and determination of CPPopt may not be possible for some patients [31].

Although determination of brain tissue oxygenation (PbtO₂) has fallen out of favor recently since better quality studies have shown equivocal benefit in TBI patients [32, 33]. In certain patients determination of mixed venous jugular bulb oxygen saturation and arteriovenous oxygen difference (AVDO₂) may be useful. Le Roux et al. [34] found that AVDO₂ that remained elevated after maximal treatment (by craniotomy or mannitol) had an increased risk of unfavorable outcome, while patients with increasing desaturation episodes had increased risk of mortality [35].

Although continuous drainage of CSF for ICHTN was shown to lower the burden of time spent at pressures above 20 cm H₂O better than intermittent drainage for pressure spikes, but it had no effect on patients' 6-month survival or GOS [36]. Interestingly, another retrospective study found higher mortality in patients with an external ventricular drain (EVD) and presenting GCS ≥ 6 [37].

Current standard of care is to monitor severe TBI patients in the setting of a modern ICU and to treat according to both clinical exam and ICP recordings. If local care options do not allow for readily available ICP monitoring, then careful attention to clinical exam along with imaging seems to be an effective alternative [7]. We usually place an ICP monitor in patients with CT findings (contusions, cerebral edema, shift, effaced cisterns) and a GCS motor score < 6 as long as the patient does not have auditory verbal agnosia and the scoring is not related to external factors such as drugs and alcohol.

At the R Adams Cowley Shock Trauma Center, we routinely critically evaluate and update a generalized treatment algorithm for TBI that is broadly based on the BTF Guidelines, best available evidence, and clinical experience (Figure 1A and Figure 1B). Medical management begins in the field and continues on arrival to the Trauma Resuscitation Unit. There after evaluating the patient, resuscitation, stabilization, and advanced imaging may show the need for an operative intervention by neurosurgery (and others). During this time airway and breathing assessment is rapidly done to ensure SpO₂ (peripheral oxygen saturation) >94% with protection of an airway, hemodynamic stabilization for SBP >100 mm Hg, and international normalized ratio (INR) and platelet counts corrected to <1.5k and >80k, respectively. If signs of herniation are present, e.g., pupillary dilation, then 500 mL of 3% hypertonic saline are delivered, and as soon as possible a head CT is obtained. Assuming there is no mass lesion with shift or malignant edema (Marshall Diffuse Injury IV; [38]) requiring immediate operative intervention, an EVD is usually placed in patients with a GCS motor score <6 not explained by reasons other than TBI.

Initial Interventions

From this point, the patients are generally managed in a critical care unit with hourly neurologic checks and ICP recordings. Initial intervention is aimed at relative homeostasis with ICP <20 mm Hg (<25 mm Hg post-craniectomy), CPP >60 mm Hg, SBP between 100 and 140 mm Hg, SpO₂ >94%, serum Na⁺ >140, and normothermia. If the patient is intubated, end tidal CO₂ monitoring is standard and correlated to PaCO₂ (partial pressure of carbon dioxide in arterial blood) and targeted within a normal range (~40 mm Hg). These laboratory values, in addition to head of bed maintained at 30 degrees, head and neck aligned, and an appropriate level of analgesia (fentanyl) and sedation with propofol (maximum 75 mcg/kg/min, measure daily myoglobin), are what we consider 'initial interventions.' CT scans are obtained again at 6 hours and 24 hours after the initial abnormal CT to test for stability. If propofol infusion syndrome or ICP control is needed for more than 7 days, then consider switching to midazolam infusion or dexmedetomidine if ICP is due to agitation [39]. Patients are at increased risk for propofol infusion syndrome if the dosage is more than 4 mg/kg/hour or is administered longer than 48 hours. The patient's condition should be carefully monitored for acidosis, rhabdomyolysis, hyperkalemia, hyperlipidemia, renal failure, and hypotension which might result in sudden cardiac arrest and death.

First Tier Therapies

If at any time ICP is greater than 20 mm Hg (or 25 mm Hg post-DC), neurosurgery is notified, initial interventions are verified, and if verification is made then the patient is ventilated to target PaCO₂ to 35 – 38 mm Hg, propofol can be raised by 5 mcg/kg/min to a maximum 75 mcg/kg/min, small fentanyl bolus can be given for pain, and if the ICP is still elevated 250 mL of 3% hypertonic saline (or 7.5% NaCl or Na acetate if hyperchloremic). Alternatively, mannitol 0.25 – 1 gm/kg can be given in a resuscitated patient. The relative merits of hypertonic saline versus mannitol for ICP lowering beyond the overall volume status of the patient are not well defined. However, at least one small RCT and a recent retrospective study have suggested that hypertonic saline may lead to more durable ICP-lowering effects following treatment as a percentage of time spent above 20 mm Hg; however, no advantage to GOS or mortality was seen [40, 41].

If the ICP is >20 mm Hg *and* motor GCS declines by 1 point or more at any time, also order a stat CT to evaluate for evolving brain injury.

Second Tier Therapies

If ICP still remains elevated above 20 mm Hg after first tier therapies, propofol is increased to a maximum 100 mcg/kg/min, bladder pressure is measured to determine if abdominal compartment syndrome is contributing to ICP, and, as a short-term bridge to the operating room, hyperventilate the patient to PaCO₂ <35 mm Hg. Recent studies suggest that hyperventilation be used only as a temporizing measure, as prolonged exposure can lead to significant ischemic problems in TBI patients [42].

If these interventions fail to reduce ICP, then according to the wishes of the family and in consultation with neurosurgery and critical care, the patient may be taken for DC.

Indication for DC, meaning what is the advantage of DC over any other treatment reasonably available to the patient, is still under investigation. Only two high quality RCTs have been published, the DECRA and the RESCUEicp trials, which are discussed at length

elsewhere in this book [43, 44]. Because the interpretation of these studies directly affects indications for DC, some salient points bear mentioning here. In the DECRA (Decompressive Craniectomy) study, a relatively early randomization to DC at 15 minutes of ICP >20 mm Hg after first tier therapy and an aggressive bifrontal DC may have contributed to worse outcomes at 6 months in the DC group than the medical management group [43]. When random selection bias for pupil reactivity was addressed in a post hoc analysis, DC still appeared at best no better than medical management alone. Since ICP was shown to be acutely reduced by DC, other factors including bifrontal DC and second tier use of DC may have confounded the results. For these and other reasons, the BTF does not recommend DC under these conditions. However, the question raised by this study was whether TBI patients with pure ICHTN refractory to medical treatment might be salvageable? The RESCUEicp (Randomized Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure) study was performed in a significantly different manner, including surgeon's choice of unilateral or bifrontal DC and use of DC as a 'last-tier' intervention after 1 to 12 hours of ICP >25 mm Hg despite maximal medical management excluding barbiturates [44]. The results of this RCT were more in line with other RCTs conducted for DC utility following malignant cerebral ischemia (please see Chapter 9 "Decompressive Craniectomy in Ischemic Stroke"), in that DC seems to save lives but at the cost of existing in a severely disabled state.

Thus a discussion with the family should address the possibility that although DC may save the patient's life, there is a significantly increased risk of severe disability or vegetative state by the time DC is typically considered. Advance directives should be part of the conversation.

Third Tier Therapies

If after second tier therapies the ICP is still elevated, the patient can be treated with barbiturate and/or with induced hypothermia. Neither intervention has led to improved outcome in most studies, yet both are powerful means to lower ICP. Although the study of Eisenberg and colleagues [1] showed that TBI patients who responded to barbiturates to lower ICP had lower mortality (92% versus 17%), the crossover design made this difference disappear when only non-crossover patients were considered. More recent studies by Majdan et al. [45] and Perez-Barcena et al. [46] highlight the fact that although barbiturates effectively lower ICP in TBI patients, other severe side effects such as hypotension offset any positive effect on outcomes. Interestingly, the medical arm of the RESCUEicp trial had a relatively high mortality rate of 48.9% where 87.2% of these patients received barbiturates versus only 9.4% in the DC group (Hutchinson et al. [44]). Patients must be intubated and have continuous ECG and EEG monitoring, along with ICP monitoring and invasive or non-invasive cardiac output monitoring. It is essential that the patient is adequately resuscitated and that fluid bolus and/or vasopressors are ready at the bedside during the typical bolus infusion of pentobarbital given the possible severe depression of cardiac output. Pentobarbital is given 1 – 5 mg/kg intravenously at a maximum rate of 50 mg/min, and can be repeated every 15 minutes until the ICP lowers or up to a maximum dose of 1000 mg or 20 mg/kg is delivered (whichever is lower). In our experience that further pentobarbital doses will only add to side effects and not affect ICP. In addition to cardiopulmonary depression, patients lose gag and cough, and often suffer

from ileus, and so should be positioned on their side and should feeding through a post-pyloric feeding tube. Motility agents such as erythromycin or metoclopramide and/or trickle feeding may be necessary.

The use of prophylactic hypothermia for TBI has been controversial as the data for universal employment have been inconclusive. Several randomized trials have utilized various cooling strategies, including timing, patient population, and head-only cooling. The most recent BTF guidelines based on a meta-analysis of seven RCTs of hypothermia versus normothermia (one Class 1, six class 2) found only low-quality evidence to suggest a benefit in outcome and thus could not recommend this for general practice. Studies exploring timing and head-only cooling remain sparse and of poor quality. However, of note in the only Class 1 RCT of Clifton et al. [47] comparing outcomes of patients with severe brain injury randomly assigned to hypothermia (cooled to 33 °C for 48 hours and then rewarmed before treatment) or normothermia groups, there was no statistically meaningful difference in outcomes between the groups as a whole, but those with craniotomy for evacuation of hematoma apparently did have better outcomes (33% versus 69%, $p = 0.02$). Follow-up post hoc analysis by this same group that included data from an earlier study in 2001 similarly showed that craniotomy patients cooled within 1.5 hours of surgery had fewer poor outcomes than those cooled slowly or kept normothermic (41% versus 62%, $p = 0.009$) [48]. Thus, even though hypothermia may present no apparent benefit for diffuse TBI other than short-term ICP reduction, certain patient subpopulations such as those with evacuated mass lesions may ultimately benefit. However, more rigorous testing of this hypothesis awaits clinical trials before widespread implementation.

Intracranial Hemorrhage

The most common non-traumatic hemorrhages within the cranial vault are intracerebral hemorrhage (ICH), intraventricular hemorrhage (IVH), and aneurysmal subarachnoid hemorrhage (SAH), all of which can lead to increased ICP. Because ICH is focal in nature, global changes in ICP tend to be less of an issue than mass effect or midline shift. However, pending any surgical intervention meeting the latest guidelines that rely heavily on the STICH trials [49, 50], medical management is focused on management of SBP to prevent further hemorrhage, correction of any coagulation abnormalities, hyperosmolar therapy with hypertonic saline or mannitol if there is a symptomatic shift or impending herniation, and use of an EVD if there is intraventricular extension or large shift of the ICH [51]. IVH can lead to hydrocephalus and the requirement of an EVD and/or hyperosmolar treatment. SAH can lead to diffuse cerebral edema as well as acute hydrocephalus that may need to be treated and monitored by EVD. The overall management of SAH and other spontaneous brain hemorrhages, beyond management of ICP, is outside the scope of this chapter.

Intracerebral hemorrhage (ICH) for the purposes of this chapter will include bleeds within the cerebral hemispheres as well as the cerebellum. Once an underlying vascular lesion or hemorrhagic mass is excluded by advanced imaging, e.g., CT angiogram, digital subtraction angiogram, and/or contrasted magnetic resonance imaging (MRI), opinion is mixed on the benefit of any craniotomy or craniectomy for supratentorial ICH. Results of the two largest trials show a small but non-significant survival benefit for early clot evacuation that may be relevant only when the prognosis is poor for declining patients with a lobar ICH

[49, 51]. Thus current guidelines recommend ICH clot evacuation in a deteriorating patient as a life-saving measure only, whose benefits to outcome are currently unclear. For a declining patient with a cerebellar ICH, the patient should be taken to the operating room immediately once any bleeding disorder is corrected and in accordance with family wishes.

Patients should be evaluated as soon as possible, and may present with any number of symptoms resembling ischemic stroke. A clinical scale such as the NIH Stroke Scale regarding ischemic stroke and ICH-specific tools such as the ICH score and FUNC score are used [52, 53]. Rapid imaging by CT is critical, as is blood pressure control (SBP <140 mm Hg once ICH diagnosis is made). Laboratory tests, especially coagulation and complete blood count studies, as well as patient history for any anticoagulants or antiplatelet agents in use are key. Any coagulopathies should be corrected according to American Heart Association Stroke Council guidelines [51]. Coagulation parameters should be corrected to an INR <1.4, platelets to >100k, or if the patient is on NSAIDS, then one six-pack of platelets should be given. If the patient is deteriorating, and following evidence of a worsening CT scan, a discussion should occur with neurosurgery and the family to determine if it is consistent with the known wishes of the patient to consider a possible life-sparing surgery that will have an unclear impact on overall outcome. This includes ICH patients with lobar, surface (<1 cm), or cerebellar ICH only. Patients with deep basal ganglia hemorrhages are generally not amenable to open craniotomy evacuation, but may benefit from a clinical trial of catheter evacuation at tertiary centers, e.g., Minimally Invasive Surgery Plus rt-PA for Intracerebral Hemorrhage Evacuation (MISTIE) trial [54]. Patients with IVH extension of ICH or large shift may develop hydrocephalus requiring EVD placement. The most recent guidelines do not recommend prophylactic antiepileptics [51].

In the ICU, standard critical care protocols for homeostasis are carried out to maintain oxygenation, blood pressure, and hemostatic, metabolic, and nutritional goals. Hourly neurologic assessment is crucial in the first 24 hours. Repeat non-contrast CT scans should occur at 6 hours and at 24 hours for stability, and neurosurgical staff should be made aware of any clinical or CT changes. Neurologic decline at any time should warrant emergent call to neurosurgery and trigger a stat CT scan.

Patients with IVH may present in a number of ways depending on whether the IVH is accompanied by an ICH. The most common complaint is headache, but severe IVH can lead to acute hydrocephalus, loss of consciousness, and death, making timely evaluation and management critical. As with ICH, rapid assessment of the patient's neurologic exam, CT scan, laboratory values with particular attention to complete blood count and coagulation parameters, and history of antiplatelet or anticoagulant use is essential. If known baseline measures have declined and evidence of hydrocephalus is present, the patient will likely need an EVD as long as blood clotting is normal and placement of the drain is consistent with known patient wishes. In general, there is little role for craniotomy or craniectomy for IVH.

Infarction

A more thorough description of the disease and a detailed analysis of the clinical data regarding DC for infarction, including the DESTINY, DECIMAL, and HAMLET trials among others, appear elsewhere in this volume. Here we summarize indications and ICU care.

A large cerebral ischemic stroke ($>80\text{ cm}^3$) in the internal carotid artery, middle cerebral artery (MCA) territory, or cerebellar hemisphere warrants special attention. Ischemic cerebral stroke above 145 cm^3 by MRI at 14 hours has been shown to pose a risk for herniation and death [55], while those $>80\text{ cm}^3$ at 6 hours may benefit from early decompression [56]. Clinical features are specific to the area affected, but even hemispheric strokes may exhibit little change to arousal. To date, no specific clinical feature has been found to track with level of consciousness; thus a thorough baseline exam is essential for further treatment. A standardized scale, such as the National Institutes of Health Stroke Scale (NIHSS) score, should be used to convey consistent patient information. Once baseline patient data have been established, changes to level of consciousness can be recorded in an ICU setting. There are no definitive criteria for DC, but it has been suggested from several prospective clinical trials that those younger than 60 years and within 48 hours of cerebral stroke may show a lower mortality if decompressed than medically managed patients; however, no patient was left without significant neurologic deficit in these trials [57]. A more recent meta-analysis of seven RCTs by Alexander et al. [58] showed that the benefit of decompression may also extend to patients older than 60. Various aspects of neurologic decline are possible in cerebral infarction, including worsening motor function, ipsilateral pupillary dysfunction, mydriasis, and adductor difficulty. Cerebellar infarct can lead to brain stem findings (pinpoint pupils, irregular breathing) and acute hydrocephalus (and death). Thus timely, accurate, and ongoing assessment is critical to patient outcomes.

On arrival to the emergency department, patients should be evaluated as soon as possible by neurological staff for initial treatment with standard of care according to the AHA Stroke Council guidelines [57]. Once diagnosed with a large cerebral or cerebellar stroke, the patient should be transferred to the ICU. Patients rarely require DC in less than 24 hours after a stroke, but if internal carotid artery stroke volume is $>145\text{ cc}$, an early neurosurgical consult may be warranted. Blood pressure management is initially guided by whether the patient is a candidate for thrombolytic therapy. If the patient is a candidate, then the recommendation is for SBP $\leq 185\text{ mm Hg}$ and diastolic blood pressure (DBP) $\leq 110\text{ mm Hg}$ with maintenance at $\leq 180/105$ for 24 hours after treatment. If no thrombolytic treatment is needed, the blood pressure can left alone, only correcting for SBP $>220\text{ mm Hg}$ or DBP $>120\text{ mm Hg}$.

In the ICU, neurological assessment is required once an hour with maintenance of homeostasis maintaining normoxia, controlling excessive hypertension or hyperglycemia according to American Heart Association Stroke Council guidelines [57, 58]. Key to patient management in this setting is recognition of cognitive decline attributable to the stroke. ICP monitoring is not required in this setting and in fact may be misleading [59]. If an EVD is placed into a patient with large cerebellar stroke who is developing signs and symptoms of hydrocephalus, it should be only a temporizing measure until the patient can be taken to the operating room for suboccipital decompression [60].

For patients with malignant hemispheric infarctions, decisions regarding DC need, above all, to take into account family and patient wishes based on a thorough discussion including reasonable expectations for outcome. Mortality as high as 78% has been reported without decompression, although perhaps confounded by withdrawal of care [61]. In years past, preference was given to those younger than 60 years and having a non-dominant hemisphere stroke given the fear of an aphasic patient, yet many people view hemiplegia as at least as bad if not worse than aphasia alone—or even death [62]. Additionally, many aphasic patients show improvement over time [63]. Stroke of the non-dominant hemisphere can also lead to

severe deficits such as abulia, neglect, and depression; thus, sidedness has become less of an issue.

Predicting which patients may progress to a malignant swelling in the 10% of patients with ischemic strokes has been associated with an NIHSS >18, early CT with infarction of >50% of the MCA territory, young age, hypertension, heart failure, and female sex [64]. Other modalities may help prognosis in the future such as serum biomarkers, CT perfusion, and cerebral microdialysis as more studies are performed to define relevant parameters.

No absolute selection criteria exist for when DC becomes necessary, but in general based on the available RCT data, patients to be considered are those having an NIHSS >16 (including altered level of consciousness on NIHSS question 1a), age younger than 60 years, less than 48 hours since onset stroke, either >50% MCA on CT or >145 cc on MRI infarcted, no surgical contraindications (coagulopathy, hemodynamically unstable), fixed dilated pupils, large hemorrhagic transformation, or limited life expectancy. Those older than 60 or at more than 48 hours can be considered on a case by case basis [65].

Cerebral venous thrombosis (CVT) is a relatively uncommon disorder accounting for <1% of all strokes [66]. Risk factors include thrombophilias, pregnancy, oral contraceptive use, infection, and malignancy. Predictors of mortality at 30 days includes depressed consciousness, hemorrhagic lesions, and deep venous thrombosis. Up to 5% of patients die in the acute phase, mainly due to large hemorrhagic lesions and diffuse cerebral edema [67, 68]. Up to 40% of CVT patients can have ICHTN [69]. Treatment is centered on anticoagulation, and data suggest that low-molecular-weight heparin may be more effective without increased risk of hemorrhage than unfractionated heparin [70]. If the patient is unstable or may have an upcoming procedure, then heparin should be used. Endovascular treatment for patients unresponsive to anticoagulation has been used with variable success, and there seems to be no advantage for patients with large hemorrhagic lesions or impending herniation [71].

DC in patients with intractable ICP and CVT has been shown to be of benefit, especially in those patients without hemorrhagic transformation or deep cerebral venous involvement [72]. There have been no RCTs for this condition, but the roughly ten published small studies have reported 0% – 30% mortality and 57% – 100% favorable outcome [73]. Even for those with hemorrhage, it can be a life-saving intervention.

Intracranial Mass

The medical management of intra- and extra-axial brain masses is subject to the properties of the focal lesion(s). If significant midline shift or posterior fossa swelling is present, then surgical debulking should certainly enter into consideration. For tumors, maintenance of eunatremia, euvoemia, and normoxia remain the underlying goals, and for lesions with significant mass effect and/or swelling, high-dose steroids such as dexamethasone 4 mg every 6 hours can be used [73]. For abscesses, use of appropriate antimicrobials remains the first line, but a large mass effect may need stereotactic drainage or debridement, or ventricular entrapment may require an EVD for CSF diversion. In case of either a mass or an abscess, the mainstays of treatment are prevention of hyponatremia or hypotension, CSF diversion if needed, hyperosmolar therapy for raised ICP or impending herniation, and medication targeted therapy to the lesion. DC in either case is not the usual standard of care, unless evacuating a large epidural empyema with contamination of the bone

flap that necessitates disposal. Conversely, DC for tumor debulking may result in fungation of the tumor [74].

Meningitis

Patients with meningitis can develop significant ICHTN, and along with antimicrobial treatment, they may require hyperosmolar treatment and/or CSF diversion through an EVD or serial lumbar puncture, if theirs is a non-obstructive presentation. Overall, dose escalation treatment of ICHTN is similar to that used for TBI, and there have been several scattered case reports of DC for intractable ICHTN over the years [75].

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH) is a disorder of unknown etiology predominantly affecting obese women of childbearing age. The primary problem is chronically elevated ICP, and the most important neurologic manifestation is secondary progressive optic atrophy, visual loss, and possible blindness. Signs and symptoms include headaches, visual loss, diplopia, tinnitus, and radicular pain in the arms. Diagnosis is made by ophthalmologic exam looking for papilledema, MRI/venography with gadolinium to rule out sinus thrombosis or mass lesions, and lumbar puncture. Treatment is aimed at preserving optic nerve function and vision. Medical therapy includes acetazolamide for ICP lowering and headache control through amitriptyline or another migraine prophylaxis agent. Surgical intervention includes optic nerve fenestration, ventriculoperitoneal shunt, or venous sinus stenting if visual function deteriorates. DC is not appropriate treatment for this condition [76].

Hepatic Encephalopathy

Hepatic encephalopathy in cirrhosis patients is characterized by personality changes, sexual impairment, and a depressed level of consciousness. The underlying mechanism is pollution of the systemic circulation with neurotoxic substances through patent portosystemic collateral vessels. Thirty to forty-five percent of cirrhosis patients will show signs and symptoms of encephalopathy as will 24% to 53% of patients who undergo portosystemic shunt surgery [77]. By the time patients are ill enough to be admitted to hospital the 3-year survival rate is a grim 23% [78]. Approximately 30% of patients dying of end-stage liver disease experience significant encephalopathy approaching coma. This is a hallmark of acute liver failure (ALF) [79]. Encephalopathy from cirrhosis and ALF share many of the same pathogenic mechanisms.

ALF is a rapid deterioration of liver function resulting in coagulopathy, with the INR >1.5, and altered mental status in a previously healthy individual. Cerebral edema, jaundice, ascites, tenderness, hematemesis, and hypotension are some of the presenting symptoms, and the critical step in treatment is the identification of a cause that will guide further treatment. For example, acetaminophen may lead to liver failure as a result of intentional or accidental overdose. In the US Acute Liver Failure study, unintentional acetaminophen use accounted

for 48% of cases, whereas 44% of cases were due to intentional use [80]. Chronic alcohol use may greatly increase susceptibility to hepatotoxicity from acetaminophen because of depleted glutathione stores. Prompt treatment with N-acetylcysteine is essential especially when patients present within 8 hours of acetaminophen ingestion; treatment with N-acetylcysteine combined with activated charcoal is effective when they present within 4 hours [81].

These patients may progress to multiorgan failure, vasoplegia mimicking septic shock, and hemorrhage, but the development of cerebral edema is the major cause of morbidity and mortality. Cerebral edema resulting from hepatic encephalopathy involves both cytotoxic and vasogenic components [82]. Elevated levels of inflammatory cytokines are often found, but hyperammonemia may be the dominant cause. Astrocytes act to detoxify the brain, converting ammonia to glutamine by glutamine synthetase, and accumulation of glutamine leads to astrocyte swelling. Release of systemic nitric oxide leads to disruption of cerebral autoregulation, increasing blood flow to the brain and also raising ICP.

Reducing elevated ammonia levels via enteral administration of lactulose might help prevent or treat cerebral edema. The occurrence of cerebral edema and ICHT in patients with ALF is related to the severity of encephalopathy [83]. Cerebral edema is seldom observed in patients with grades I – II encephalopathy that is characterized by lethargy, slowed responses, loss of inhibition, asterixis, and ataxia at worst. The risk of edema rises to 25% – 35% with progression to grade III (somnia, aggression, Babinski, rigidity) and increases to 65% – 75% (or more) in patients reaching grade IV coma. The primary purpose of ICP monitoring is to detect elevations in ICP and reductions in CPP so that interventions can be made to prevent herniation while preserving brain perfusion. The ultimate goal of such measures is to maintain neurologic integrity and to prolong survival while awaiting the receipt of a donor organ or recovery of sufficient functioning hepatocyte mass. Additionally, refractory ICP and/or decreased CPP are considered contraindications to liver transplantation in many centers. ICP is managed initially with the use of mannitol, and it is effective in the short term to decrease cerebral edema. The dose may be repeated once or twice, as needed, provided that serum osmolality has not exceeded 320 mOsm/L. Volume overload is a risk with mannitol use in patients with renal impairment and may necessitate the use of dialysis to remove excess fluid.

If life-threatening ICP is not controlled with mannitol infusion and other general management as outlined above, hyperventilation may be instituted temporarily in an attempt to acutely lower the ICP and to prevent impending herniation. Hyperventilation to reduce the PaCO₂ to 25 to 30 mm Hg can quickly lower ICP via vasoconstriction, causing decreased cerebral blood flow, but this effect is short-lived.

Other therapies used to decrease ICP, but not routinely recommended, may be considered in refractory ICH. These include hypertonic saline, barbiturates, and hypothermia.

In the absence of bleeding, it is usually not necessary to correct clotting abnormalities with fresh frozen plasma (FFP). The exception is when an invasive procedure is planned or in the presence of profound coagulopathy (INR >7). Bleeding abnormalities can occur when coagulation factors are less than 17% and may have to be corrected with a 15 mL/kg FFP infusion. Low levels of fibrinogen (80 mg/dL) may need to be corrected with cryoprecipitate, and for platelet levels between 10k and 80k, six to eight donor units of platelets are infused before or upon start of an urgent procedure. In certain cases of excessive bleeding or anticipated procedure, recombinant factor VII (4 mcg/kg) may need to be used in patients refractory to FFP alone.

DC in general is not considered in this patient population because of the usual accompanying coagulopathy. Neurosurgery staff are generally consulted to place ICP monitors for the management of cerebral edema and to aid triage to liver transplant when indicated. Although opinion is mixed on the utility of ICP monitors in ALF patients as no effect on long-term outcome has been seen in retrospective studies, such monitoring may aid in selection for transplantation [84].

CONCLUSION

Medical management of ICHTN should be carried out in an ICU setting, where close clinical assessment of the patient and careful attention to traditional and neurologic vital signs can take place. Surprisingly few high-quality RCTs have been done to directly address some of the most important questions, such as optimal ICP thresholds for treatment, optimal hyperosmolar therapy, and timing of DC. Most clinical decisions are based on smaller lower-quality trials and case series, as well as local clinical experience. Future care of these patients may very well rely on an individualized treatment algorithm to optimize neurologic vital signs, where a rigid ‘one size fits all’ protocol is no longer sufficient to improve outcomes. International collaborative efforts underway, such as Center-TBI (<http://www.center-tbi.eu>) and TRACK-TBI (<https://tracktbi.ucsf.edu>), may ultimately prove necessary to analyze ‘Big Data’ sets across the spectrum of TBI patients to help form more customized treatment.

PREOPERATIVE AND POSTOPERATIVE NURSING CARE OF PATIENTS UNDERGOING DECOMPRESSIVE CRANIECTOMY

Karen A. McQuillan* and Tya Schoppe†

R. Adams Cowley Shock Trauma Center, University of Maryland Medical Center,
Baltimore, MD, US

ABSTRACT

Nurses are vital members of the health care team that cares for patients with severe traumatic brain injury before and after decompressive craniectomy. To achieve optimal outcomes for these patients, the team is focused on avoiding secondary brain injury, preventing and treating potential complications, and enhancing emotional, cognitive, and psychosocial aspects. This calls for nurses to recognize and interpret changes in the patient's clinical status and alterations in monitored variables, prompting notification of the provider and timely intervention. Nurses must be knowledgeable about the desired therapeutic endpoints, nursing implications, and potential complications associated with medically prescribed treatments and nursing care used to treat patients with severe traumatic brain injury through resuscitation, critical care, and as the patient transitions from acute care or progresses to brain death. Communication about the patient's response to interventions is essential to guide sound clinical decision making aimed at achievement of optimal patient and family outcomes.

Keywords: nursing care, brain injury, decompressive craniectomy

INTRODUCTION

Nurses are an integral part of the health care team caring for patients before and after decompressive craniectomy (DC). The nurse must draw on a strong knowledge base and highly developed critical thinking skills to perform astute patient assessments that identify detrimental trends in monitored parameters and subtle changes in the patient's clinical examination findings. Once identified, the nurse must react swiftly to the unfavorable findings and work collaboratively with other members of the health care team so that appropriate interventions are instituted. In addition, nursing care is essential to prevent, quickly recognize, and appropriately intervene to treat potential complications that can occur in patients with severe brain injury.

GOALS OF CARE

Following brain injury a principal goal of nurses together with others on the interdisciplinary health care team is to prevent secondary injury. Unlike primary brain injury that occurs immediately upon impact and for which there is no direct treatment, secondary brain injury can evolve or occur hours to days after the primary injury and may be preventable. Factors that exacerbate progression of the intracellular pathologic cascade of events leading to delayed cell death such as hypoxia, hypotension [1, 2, 3, 4], intracranial hypertension [1, 5, 6, 7], hyper- or hypo-capnea [1], fluid and electrolyte imbalance, coagulopathy [8, 9], hyper- or hypo-glycemia [10, 11], hyperthermia [3, 7, 12], seizures [1], anemia [13, 14], and ischemia may be prevented to avoid secondary brain injury [15]. Some neurons are compromised functionally, but not disrupted mechanically following primary brain injury. If given an optimal environment for survival, these neurons may recover. These same neurons are particularly vulnerable to secondary brain injury, especially when exposed to factors that make delayed cell death more likely. For this reason, a primary aim in the management of brain injury is prevention of secondary injury [15, 16].

Nurses and the rest of the health care team also strive to prevent, quickly recognize, and appropriately treat potential complications that may exacerbate secondary brain injury and can increase mortality and morbidity. Finally, the health care team aims to sustain and enhance the emotional, cognitive, and psychosocial aspects of patients with brain injury. Attainment of these goals fosters achievement of optimal patient outcomes.

PREOPERATIVE NURSING CARE OF PATIENTS UNDERGOING DECOMPRESSIVE CRANIECTOMY

Clinical Assessment

After initial resuscitation interventions to ensure a patent airway, effective ventilation, and sufficient circulation, attention is then given to obtaining a neurologic assessment. Neurologic assessment should include a baseline clinical examination followed by serial reassessments to identify changes in the patient's condition. The baseline neurologic

evaluation should include information about the mechanism of brain injury and the prehospital course, including the examination findings and interventions initiated prior to hospitalization. As soon as a knowledgeable family member or significant other is contacted, a health history should be obtained to determine any premorbid conditions and medications taken before the injury that could affect treatment decisions.

Clinical examination, while a seemingly basic neurologic assessment strategy, constitutes an important aspect of assessing function of the injured brain. Nurses play a key role in performing a comprehensive initial neurologic examination and ongoing serial reassessments that allow detection and, when appropriate, communication to the provider of changes in the patient's condition. Major components of the clinical neurologic examination include assessment of the following: level of consciousness, motor and sensory function, eye and pupil signs, other key reflexes assessing cranial nerve function, and vital signs.

Level of consciousness assessment includes evaluation of arousal and awareness or cognition. The least noxious stimulus needed to elicit a response from the patient determines arousal. The patient may be alert and respond when approached or may require a stimulus, such as voice, shaking, peripheral pain, or deep central pain to elicit a response. If the patient is arousable, attempts can be made to evaluate awareness by assessing various cerebral cortical functions (e.g., affect, orientation, memory, intellectual ability).

Motor function is first evaluated by noting the patient's response to the stimuli applied when assessing arousal. The best possible response is the ability of the patient to consistently follow commands (e.g., protrude the tongue or hold up two fingers). Some patients may not follow commands but can localize to a stimulus, and others with an even lower level of consciousness may withdraw or have a normal flexor movement. Even worse motor responses include abnormal flexion (i.e., decorticate posturing), abnormal extension (i.e., decerebrate posturing), or no motor response. Also symmetry of motor strength, as well as muscle tone and any abnormal movements (i.e., seizures, tics, or tremors) should be noted. In patients who are alert and able to follow commands, more thorough assessment of awareness, sensation, cerebellar function, and the cranial nerves can be performed.

Generally, in minimally responsive patients receiving sedative or analgesic infusions, the nurse momentarily halts those agents known to suppress the neurologic status in order to obtain an optimal neurologic assessment. If the patient does not tolerate stopping these drugs as evidenced by monitored neurologic (e.g., intracranial pressure), hemodynamic, and/or respiratory parameters exceeding acceptable thresholds, this should be communicated to the provider. A determination can be made whether, at least temporarily, these drugs should not be discontinued before attempting a neurologic examination. After the examination is complete, the neurologic findings should be well documented so that other health care team members can accurately determine any changes in the patient's condition. To avoid confusion, vague terminology to describe responsiveness, such as lethargic, obtunded, and semi-comatose, should be avoided. Instead, what should be recorded is a clear description of both the stimulus needed to elicit a response and the motor response to the stimulus. Because assessment findings may be interpreted differently by various nurses and other health care team members, it is best that when handoffs occur between shifts and when transitioning between care areas, a neurologic assessment be done with the off-going and oncoming nurses present.

Cranial nerve motor/sensory function can be assessed by evaluating the direct and consensual light reflex, corneal reflex, facial grimace, gag reflex, and cough reflex. Absence

of the corneal reflex triggers the nurse to take care to protect the cornea by instillation of prescribed ophthalmic lubricants, taping the eyelid closed, or use of an eye shield. An impaired gag or cough reflex alerts the nurse to increased risk for patient aspiration.

Abnormal eye and pupil findings can be ominous signs of neurologic deterioration, especially when accompanied with other evidence of worsening neurologic examination. Change in pupil shape from a round to an oval or irregular shape can signify impending transtentorial herniation causing third cranial nerve compression. Likewise, a delayed or sluggish pupil response to light is an early warning sign that the pupil may soon become nonreactive to light. Nurse recognition and provider notification of these subtle early pupil signs are important so that interventions intended to halt further brain damage can be promptly administered.

Manual evaluation of pupil size and reactivity to light is plagued by inconsistencies within and between those performing assessments and by errors in detecting the light reflex in certain conditions [17, 18]. Therefore, some institutions have adopted use of a handheld automated pupillometer to provide objective measures of pupil size and reactivity to light. Meeker and colleagues [17] determined in a trial of 20 patients that the pupillometer was more reliable and accurate than manual pupil checks to measure pupil size and reactivity. The pupillometer compares the patient's measures of pupil maximal size, latency, average and maximum constriction, and dilatation velocity to a multidimensional normative model and reports this value as the neuropupillary index (NPi) [19]. Normal NPi is ≥ 3.0 . An NPi score < 3.0 is abnormal and may reflect intracranial pressure elevations and so should be reported to the provider [19].

Regardless of the method used to evaluation pupil size and reactivity, nurses and other clinicians need to remain cognizant of the effects that other premorbid conditions, drugs, and associated injuries may have on pupil size and reactivity. For example, alcohol use, opiate administration, and instillation of ophthalmic miotic drugs may cause pupil constriction, whereas amphetamine use, atropine administration, and instillation of cycloplegic agents are associated with pupil dilation. Knowledge of drugs the patient may have taken prior to admission or that have been administered to the patient should be well documented and communicated to other clinicians before they perform their neurologic exam.

Vital signs, including heart rate and rhythm, blood pressure, respiratory rate, as well as, pulse oximetry (SpO_2), and end tidal carbon dioxide (ETCO_2) are typically monitored continuously in critically ill patients with severe brain injury. This enables rapid detection of deterioration in these parameters. Efforts to quickly intervene to remedy any detrimental alterations are essential to prevent or treat hypoxia, hypercapnea, and poor perfusion, all of which increase secondary brain injury.

Core body temperature and, if available, brain temperature should also be monitored at frequent intervals or, ideally, continuously. The inflammatory response to injury, presence of blood in the brain, and damage to the temperature-regulating hypothalamus can trigger fever or hyperthermia in the brain-injured patient [12]. Reportedly, core body temperature is 0.39°C to 2.5°C less than the temperature measured in the brain [20]. The most accurate methods for measuring core body temperature are with a intravascular (e.g., pulmonary artery catheter), bladder, esophageal, or rectal sensor [21]. Regardless of the method used, the nurse must confirm proper temperature sensor placement and function to ensure accurate measures.

Standardized assessment tools that use neurologic clinical examination findings to quantify the severity of injury or neurologic disability are often employed with brain injured

patients. The internationally recognized Glasgow Coma Scale (GCS) is the most commonly used tool to score and communicate the severity of brain injury or degree of consciousness [22, 23]. A decline in the GCS score should trigger notification of the provider to determine if additional interventions are warranted. Even those who created the GCS suggest that in the acute phase, pupil and eye movement and cerebral and brain stem function should be used in addition to the GCS to evaluate overall neurologic function [23]. Some have proposed use of alternative scales to evaluate consciousness, such as the Full Outline of UnResponsiveness (FOUR) Score. The FOUR score incorporates brainstem reflexes, breathing patterns, and a variation on measures related to motor and eye response, and it eliminates a verbal response score [24]. Serial scores can indicate the patient's response to therapy as well as signal whether the overall neurologic status is improving or worsening over time. Consideration should always be given to factors that can confound an accurate score, such as administration of analgesics, sedatives, paralytics, or anesthetics, endotracheal intubation, aphasia, language incomprehension, inability to hear, periorbital edema, drug intoxication, injury to the eye, face, cranial nerves or spinal cord, dementia, developmental impairments, psychiatric disorders, and inability to speak [25]. Presence of such variables should be well documented with the score.

In addition, the nurse must remain vigilant in recognizing and responding to other intracranial and extracranial complications or associated injuries that threaten to promote secondary brain injury or that could adversely affect the neurologic examination. For example, pulmonary complications; hemodynamic instability, coagulopathy, anemia, fluid and electrolyte imbalance, elevated or reduced glycemic states, infection, and seizures should raise concern. To reduce risk of secondary brain injury, when these complications are recognized, they should be reported to the provider and interventions to remedy them should be promptly initiated.

Neurodiagnostics and Monitoring

Clinical neurologic assessment findings raising concern for brain injury typically prompt providers to order diagnostic studies. Generally, a computerized tomography (CT) scan of the brain without contrast is the imaging modality of choice in the resuscitation phase of trauma care. The CT scan generally identifies most brain pathology, particularly that which may require medical or surgical intervention, such as hemorrhage, contusion, cerebral edema, pneumocephalus, or brain herniation. Additional follow-up CT scans may be prescribed as well to follow the progression of brain injury or to investigate the cause of neurologic deterioration. An angiography, CT angiography, or magnetic resonance angiography may be prescribed when vascular injuries are suspected. When the CT scan does not demonstrate findings that explain the patient's poor neurologic status, magnetic resonance imaging (MRI) may be requested to better visualize areas of the brain (e.g., the brainstem, base of the brain) and injuries (e.g., microhemorrhages accompanying diffuse axonal injury, nonhemorrhagic lesions of the parenchyma, acute infarction, subacute or chronic hemorrhage) not seen as well on CT [26].

The nurse generally coordinates the transport of the patient for diagnostic studies. Before leaving the unit with the patient, the nurse should verify the test to be done and the readiness of the personnel to perform the study. It is also vital that the nurse ensure the patient can

safely tolerate the travel and the diagnostic procedure. If the patient has significant hemodynamic or respiratory instability, it is best to stabilize the patient prior to transport. Also, the nurse needs to be sure the patient will tolerate being supine and flat for the duration of the study. Placing the patient in this position and evaluating the effect on hemodynamic, respiratory, and, if available, intracranial monitored parameters best assesses this readiness prior to transport. If going for MRI, typically a checklist is completed to assess if the patient has any contraindications for the study and to insure the test can be safely performed. All members of the health care team who will accompany the patient on the transport, required equipment, and prescribed medications needed during the trip should be assembled. The nurse should closely monitor the patient throughout the transport and for the duration of the study.

Based on clinical examination and neurodiagnostic findings, the provider may decide to place an intracranial pressure (ICP) monitor. A fundamental aspect of care for patients with severe traumatic brain injury (TBI) in developed countries has been to monitor ICP and intervene to reduce intracranial hypertension. Because a number of studies have shown that intracranial hypertension causes secondary brain injury, prompt recognition of it and intervention to alleviate it are important to promote optimal neurologic outcomes for patients [1, 5, 6, 7]. Controversy still surrounds use of ICP monitoring following TBI. While some studies demonstrated a survival advantage when ICP monitoring is used [27, 28], others have not [29, 30]. A trial done by Chesnut and colleagues [29], known as the BEST-TRIP trial, randomized patients with severe TBI in South America to receive treatment for intracranial hypertension based on monitored ICP or on imaging and clinical examination findings. Results showed no significant difference in outcomes between the two groups although the number of brain-specific treatments was significantly greater in the imaging/clinical examination group [29]. A follow-up consensus-based interpretation of the BEST-TRIP study stressed that this research compared two ICP treatment protocols, not ICP monitoring and noted the results should not change practice of those currently monitoring ICP. These findings highlight the need for further research on use of ICP monitoring [31].

The most recent evidence-based Guidelines for Management of Severe Traumatic Brain Injury, 4th edition, recommend (Level IIB) that ICP monitoring be used to manage severe TBI to decrease mortality in-hospital and 2 weeks after injury [1]. While lacking the evidence to support a formal recommendation in the 4th edition of the Guidelines, the recommendations for when ICP monitoring is indicated were carried over from the 3rd edition. These recommendations are that ICP monitoring is indicated in all salvageable patients with a GCS score of ≤ 8 and an abnormal CT scan (i.e., contusions, hematoma, swelling, compressed basal cisterns, or brain herniation); and in patients with a GCS score of ≤ 8 with a normal CT scan when at least two of three findings are noted at admission: (1) older than 40 years of age; (2) abnormal posturing on one or both sides; (3) systolic blood pressure below 90 mm Hg [1, 32]. An ICP monitor may also be placed at the physician's discretion (e.g., when the patient has a GCS of 9 but there is concern about increased intracranial hemorrhage or swelling and a prolonged surgical intervention is planned).

Currently there are four types of transducers that can transmit pressure data from inside the cranium to an outside monitor: the fluid-filled or hydraulic, fiber optic, miniature strain gauge, and pneumatic transducer systems. Each type of transducer has specific nurse and provider implications to consider during insertion and maintenance [33–36] (see Table 1).

Table 1. Description, advantages, disadvantages and implications of using different intracranial pressure monitor transducers.
References [33, 34, 35, 36]

Type of transducer description	Advantages	Disadvantages	Implications for insertion and maintenance
Fluid filled or Hydraulic system Uses static fluid column to transmit pressure from within the cranium to an external strain gauge transducer	• Inexpensive • Can be re-zeroed after insertion by turning the system stopcocks to close the transducer to the patient and opening the transducer to atmospheric air then zeroing the monitor	• Air bubbles, blood, brain tissue and other debris may get into the fluid column or transducer or the system may have loose connections or be kinked dampening the ICP waveform and causing inaccurate measures • Requires the external transducer be leveled with the external anatomic reference point corresponding to the distal tip of the fluid filled system • Risk for introduction of infectious organisms into fluid filled system causing device related intracranial infection	• Prior to attaching to the patient ensure system is primed with sterile preservative-free normal saline using syringe no larger than 30 ml, ensuring all air is expelled from the tubing and transducer. Use a flushless transducer and never use a flush solution or pressure bag which causes risk for inadvertent intracranial infusion of fluid • Reassess frequently to ensure transducer is leveled with a consistently used external anatomic landmark. When used with intraventricular placement the Foramen of Monroe is the zero reference level and the tragus of ear or outer canthus of the eye is typically selected as the consistent external landmark for leveling. Use a carpenter's level or laser to ensure accuracy of the transducer placement with the landmark. • Re-zero the transducer each shift, after temporarily disconnecting the patient from the monitor and when troubleshooting questionable readings. • Inspect the system for kinks, leaks, and the presence of air bubbles, blood or debris that may skew accuracy of measures. • Avoid introducing infection by employing strict sterile technique during insertion and manipulation of the system, ensuring snug connections, using dead-enders over any openings and minimizing system interruptions • If a deadender is removed from an opening (i.e., during re-zeroing), sterile gloves should be worn and a new sterile dead ender should be applied. [33, 34]

Table 1. (Continued)

Type of transducer description	Advantages	Disadvantages	Implications for insertion and maintenance
Implantable Transducer Catheter Systems A. Fiberoptic Transducer Tipped Monitoring System Uses fiberoptics to transmit pressure from a transducer embedded at the tip of the intracranially placed catheter to a bedside monitor B. Miniature Strain-Gauge Transducer-tipped System ICP is transmitted electronically from a miniature strain-gauge pressure sensor at the end of the catheter to an external bedside monitor	- Eliminates complications inherent in the fluid filled system - Closed system may reduce risk of intracranial infection - No leveling of transducer required - Can be placed in brain parenchyma	- Unable to re-zero after insertion - Drift in measured pressures over time - Catheter can become dislodged, damaged or have technical malfunction	- Must be zeroed prior to insertion - Secure the catheter to patient to prevent dislodgement - Avoid kinking to prevent catheter breakage
Air-pouch (Pneumatic) Sensor ICP is transmitted thought the walls of a small air filled pouch at the tip of the catheter that is then converted to an electrical signal by a transducer in the connected ICP monitor.	- Eliminates complications inherent in the fluid filled system - Closed system may reduce risk of intracranial infection - No leveling of transducer required - Automatically re-zeros at regular intervals - Can be placed in brain parenchyma - Also measures brain compliance	- One study comparing the air-pouch sensor to the fluid filled showed a trend toward lower readings with the air-pouch sensor as ICP increased [35] - Violation of the air bladder can occur [36]	Secure sensor to prevent dislodgement or damage

Intracranial pressure monitors may be placed in the ventricle, brain parenchyma, subdural/subarachnoid space, or epidural space. Intraventricular catheters (IVC), typically placed in the anterior horn of a lateral ventricle, are considered the gold standard for measurement of ICP [16, 36]. When the IVC is placed in this location, ICP can be monitored and cerebrospinal fluid (CSF) can be drained to reduce intracranial hypertension. Placement of an IVC may be difficult if the patient's ventricles have shifted or are compressed, and each attempt at insertion increases the risk for intracerebral hemorrhage or additional tissue injury. This location for ICP monitor placement also carries a high risk for intracranial infection [1, 16, 33, 37]. Intraparenchymal placement of a fiber optic or micro-strain gauge sensor is suggested to be second only to intraventricular devices with regard to accuracy, reliability, and cost [32]. Monitors placed in the brain parenchyma tend to be quick and easy to insert even when the ventricles are compressed. Although less so than the more invasive IVC, the intraparenchymal monitors carry risk for intracranial infection and for hemorrhage at the site of insertion. The greatest disadvantage to ICP monitor placement in the brain tissue is the inability to drain CSF. Typically, subdural/subarachnoid and epidural locations for monitoring ICP are less attractive options since they tend to be less accurate than intraventricular location [32]. Nurses assisting with the ICP monitor insertion and caring for the patient after placement should be aware of the possible complications so they can take appropriate actions to minimize risks and can remain vigilant for evidence of these problems.

Prior to ICP monitor insertion, the nurse should ensure any abnormal patient coagulation parameters are reported to the provider. Depending on the degree of coagulopathy, there may be a need to correct coagulation before ICP monitor insertion to prevent triggering intracranial hemorrhage. In non-emergent cases, consent for monitor insertion should be obtained from the legally authorized representative, and a time out should always be performed. The nurse can assist with positioning the patient for the procedure and provide prescribed medications. It is important that a baseline neurologic examination be completed before and then after placement of the ICP monitor. Ideally, a protocol that reflects best practices to avoid complications related to the insertion and maintenance of the ICP monitor should be developed and routinely used. Hepburn-Smith and colleagues [37] found that although there was variability between protocols used for insertion and maintenance of external ventricular drains (EVD) to monitor ICP at ten different facilities, each site reported a significant reduction in EVD-related infections after protocol implementation. All protocols included a number of interventions to reduce risk of infection and addressed identified deficiencies in their prior practice [37].

Table 2 lists recommended best practices for insertion and maintenance of EVDs [1, 33, 34, 37, 38, 39]. Some organizations have found use of checklists; intervention bundles, and EVD supply carts that can be moved near the bedside helpful in achieving compliance with best practice protocols. Adherence to the established protocols can be promoted by engaging the entire multidisciplinary team in infection reduction efforts such as developing the protocol, providing regular staff education, validating staff competency, and monitoring protocol compliance- and EVD-related complications [37].

Table 2. Recommended best practices for insertion and maintenance of external ventricular drains. References [1, 33, 34, 37, 38, 39]

Recommendations for Insertion
• Prior to the procedure evaluate coagulation parameters and notify the provider of abnormalities
• Consider use of an antimicrobial-impregnated catheter for EVD to prevent catheter related infection (level III recommendation in the Guidelines for Management of Severe Traumatic Brain Injury)
• Position patient with head up 30-45 degrees, head midline and immobilized
• Administer any prescribed antibiotics, analgesic and sedatives
• Monitor vital signs including heart rate and rhythm, respiratory rate, blood pressure, pulse oximetry and end tidal CO₂ throughout and after the procedure
• Assess neurologic examination before, as able during, and hourly or as prescribed after the procedure. Notify the provider if deterioration in the exam findings are noted
• Perform a time out
• Ensure adherence to strict sterile technique and maximal barrier precautions during insertion – When possible close the doors and limit personnel in the room where the procedure is taking place – All staff in the room should perform hand hygiene and wear a hat, eye protection and mask – Provider placing the device and anyone assisting should have a gown, hat, mask, eye protection, and sterile gloves – Clip hair around the EVD – Scrub surgical site with antimicrobial solution. Chlorhexidine is a recommended option. – Use a broad sterile drape around the protected surgical site
• Use an EVD insertion checklist
• Typically the IVC is tunneled under the scalp away from the insertion site to reduce infection risk
• Use a chlorhexidine impregnated patch and bio-occlusive dressing at the insertion site and have competent personnel change dressing weekly or when non-adherent
• A CT scan may be ordered following the procedure to verify placement and assess for any complications
Rec Recommendations for Maintenance
• Ensure stopcocks are properly positioned for prescribed drainage
• Ensure the transducer and zero point of the drainage system are leveled at the external anatomic landmark for the Foramen of Monroe using a level or laser.
• Hourly or as prescribed assess and record the ICP, CPP, neurologic status, drainage amount and character. Notify the provider of sustained ICP elevations, CPP persistently outside desired range, or unexpected change in neurologic status, CSF drainage or character
• Clearly mark the EVD tubing so medications are not mistakenly administered into the drain
• Ensure drainage system is properly positioned and secured to prevent over drainage. Explain to visitors and other healthcare personnel not to change the height of the bed without assistance to re-level the EVD.
• Minimize risk for infection – Adhere to strict aseptic technique with any manipulation of the EVD – Minimize accessing or manipulating the EVD system and the length of time the EVD is in place – Assess the drainage system to ensure connections are snug and there are no leaks – Ensure insertion site dressing is dry and intact and changed per institutional policy. Observe insertion site for infection or CSF leak and if noted, notify the provider – Only change the drainage bag when nearly full – Obtain CSF samples only when indicated from the distal port of the EVD
• The EVD or the drainage system should not be changed at any regular interval but a change in the drainage system is indicated if it becomes inadvertently disconnected
• Provide ongoing staff education
• Regularly assess compliance with EVD maintenance
• Monitor EVD related infection rates

After placement of an IVC, CSF can be drained continuously or intermittently. The 4th edition of the Guidelines for Management of Severe Traumatic Brain Injury provides a Level III recommendation that continuous drainage of CSF with an EVD system zeroed at the

midbrain may lower the ICP burden better than when drainage is performed only intermittently [1]. When continuous drainage is prescribed, stopcocks of the EVD are positioned to keep the drain open, and CSF automatically empties into the drip chamber once ICP exceeds a predetermined level. The provider should specify the desired level at which the air–fluid interface of the CSF drip chamber should be positioned above the designated external landmark for the foramen of Monro (e.g., tragus, outer canthus of the eye). CSF drainage should be temporarily stopped to obtain an accurate measure and waveform. When intermittent CSF drainage is prescribed, the system is kept closed to drain and the transducer is kept open to the patient to enable continuous ICP monitoring. The provider's orders should specify the ICP value that should prompt drainage, as well as how long the system should remain open or how much CSF should be drained before reclosing the system. The nurse needs to closely monitor and record the amount and character of CSF drained and should notify the provider if the character of the drainage changes (e.g., more bloody or cloudy), if drainage stops, or if there is an abrupt increase.

Once in place, the ICP monitor provides data that can help detect worsening brain pathology (e.g., cerebral edema or hematoma expansion) and guides treatment. It is vital that the nurse know how to interpret the data and how to react to abnormal findings. A numeric ICP value is displayed as well as an ICP waveform. To acquire an accurate ICP pressure measure and waveform with an IVC, the stopcocks in the system must be positioned to have the drain off and the transducer open to the patient. Generally, the ICP is recorded hourly or as prescribed. If the patient has a sustained ICP elevation above 20 mm Hg, the provider should be notified and the numeric value should be recorded at more frequent intervals, such as every 15 minutes [33]. The Guidelines for Management of Severe TBI, 4th edition, recommend that 22 mm Hg serve as the threshold for initiating treatment to reduce intracranial hypertension since ICP values above this level are associated with higher mortality [1]. When interpreting numeric ICP and collaborating with the provider to make treatment decisions, the patient's clinical examination and CT scan findings should be taken into consideration [1]. The nurse can determine if a recent event such as suctioning or turning may have contributed to a transient ICP elevation that will likely return to normal in a short while. Attempts should be made to reduce ICP with simple interventions like better positioning the patient or reducing noxious stimuli to effectively normalize the ICP. It is important the nurse keep the provider informed of sustained intracranial hypertension or a persistent inability to provide essential care (e.g., pulmonary hygiene) to the patient because of ICP elevations.

Figure 1. ICP wave form, please see text. (Used with permission from McQuillan KA, Thurman PT. Traumatic Brain Injury. In: McQuillan KA, Makic MBF, Whalen E, editors. Trauma Nursing: From Resuscitation Through Rehabilitation. 4th ed. St. Louis, Saunders Elsevier; 2009. p. 481.)

Figure 2. ICP waveform with reduced compliance, please see text. (Used with permission from McQuillan KA, Thurman PT. Traumatic Brain Injury. In: McQuillan KA, Makic MBF, Whalen E, editors. Trauma Nursing: From *Resuscitation Through Rehabilitation*. 4th ed. St. Louis, Saunders Elsevier; c2009. p. 481.)

The ICP waveform should also be carefully assessed and considered when making decisions about care. (Figure 1) These waves correlate with cardiac systole and diastole and originate from pulsations of the cerebral vasculature. Normally each ICP waveform has three peaks. The first peak, P1, is the percussion wave that has fairly consistent amplitude. The second peak, P2, is the tidal wave, which normally has lower amplitude than P1, but the height of the peak can be more variable depending on brain compliance. The third peak, P3, is the dicrotic wave that occurs with closure of the aortic valve, and this wave typically tapers back to baseline [33]. The amplitudes of the waves rise in response to elevations in ICP. As brain compliance decreases, the amplitude of P2 exceeds that of P1 or P3, making the ICP waveform appear more rounded [33, 40] (Figure 2). When the ICP waveform configuration shows P2 equal to or greater than P1, the nurse should suspect that the patient's compliance or brain compensatory capacity is low, suggesting the patient may have sustained ICP elevations as a result of interventions likely to increase ICP (e.g., putting the head down, suctioning).

Figure 3. Lundberg type C waves, please see text. (Used with permission from McQuillan KA, Thurman PT. Traumatic Brain Injury. In: McQuillan KA, Makic MBF, Whalen E, editors. Trauma Nursing: From *Resuscitation Through Rehabilitation*. 4th ed. St. Louis, Saunders Elsevier; c2009. p. 482.)

In addition to analyzing the configuration of individual ICP waves, observing trends in ICP can also be valuable for figure captions. C waves are rhythmic fast waves that correspond with blood pressure changes and are believed to have no clinical significance (Figure 3). B waves are sudden elevations in ICP up to 20 to 50 mm Hg for a few seconds that occur every 30 seconds to 2 minutes (Figure 4). They may signify poor brain compliance and precede the more pathologic A waves. A waves are characterized by ICP elevations as high as 50 to 100 mm Hg for 5 to 20 minutes (Figure 5). During these high plateaus, CPP is compromised and immediate intervention to reduce ICP is necessary.

Figure 4. Lundberg type B waves, please see text. (Used with permission from McQuillan KA, Thurman PT. Traumatic Brain Injury. In: McQuillan KA, Makic MBF, Whalen E, editors. Trauma Nursing: From Resuscitation Through Rehabilitation. 4th ed. St. Louis, Saunders Elsevier; c2009. p. 482.)

Figure 5. Lundberg type A waves, please see text. (Used with permission from McQuillan KA, Thurman PT. Traumatic Brain Injury. In: McQuillan KA, Makic MBF, Whalen E, editors. Trauma Nursing: From Resuscitation Through Rehabilitation. 4th ed. St. Louis, Saunders Elsevier; c2009. p. 482.)

A dampened ICP waveform, while not unusual after DC, prior to this intervention suggests a dysfunction of the monitoring system. The nurse should troubleshoot the system methodically looking for evidence of leak, kinks, or of air, blood or debris in the fluid-filled set up. Also consider malfunction of the pressure cables or monitor. If no problem is found and after re-zeroing the external transducer the problem is not alleviated, the provider should be notified. The accuracy of the numeric value should be questioned while the waveform is dampened.

Monitoring ICP also offers the ability to quickly calculate cerebral perfusion pressure (CPP) by taking the mean arterial blood pressure (MABP) and subtracting the mean ICP from it. CPP is the pressure gradient needed to drive blood and the essential nutrients it carries to

the brain. In healthy individuals who have intact pressure autoregulation, the cerebral blood vessels are able to autoregulate their diameter to maintain a constant cerebral blood flow despite fluctuations in pressure as long as the CPP is maintained at 50 to 150 mm Hg. Brain injury disrupts normal cerebral autoregulation, at times causing a direct correlation between pressure changes and alterations in cerebral blood flow. The Guidelines for Management of Severe TBI recommend (Level IIB) maintaining a CPP range of 60 to 70 mm Hg for survival and optimal outcomes [1]. Minimal optimal CPP for a patient is not clear but likely depends on the autoregulatory status of the brain-injured individual [1]. When CPP is insufficient due to low blood pressure and/or high ICP, perfusion to the brain is compromised and ischemia can occur causing secondary brain injury. Extremely high CPP can also be detrimental to outcomes. Aggressive efforts to elevate CPP above 70 mm Hg have been shown to cause greater incidence of adult respiratory distress syndrome (ARDS) and is therefore not recommended [1, 41]. When CPP fails to remain at the desired therapeutic level, the nurse should promptly notify the provider to take actions that lower ICP and/or raise MABP to achieve sufficient perfusion pressure.

Optimal CPP may vary among patients and fluctuate over time, suggesting the need to individualize desired CPP thresholds [15, 42]. Again the autoregulation status of the patient is another likely determinant of the optimal CPP level [1]. Therefore, other measures such as the cerebral oxygenation, cerebral blood flow, or pressure reactivity index (PRx) may be helpful in determining the best CPP for a specific patient [42].

Multiple monitoring tools may be used simultaneously to provide better insight into the injured brain's physiology so that treatment can be targeted to correct alterations quickly before significant secondary injury occurs [15]. Table 3 highlights various monitoring tools that may be used for multimodal monitoring and some key advantages and disadvantages of each [43]. Additional research is still warranted to close knowledge gaps related to exact treatment thresholds and how to best integrate and use the data provided from some technologies [1]. The reader is encouraged to refer to the chapter on Multimodality Monitoring in Decompressive Craniectomy for Traumatic Brain Injury and Stroke for more detail about various monitoring strategies that may be used together to monitor and guide treatment of brain-injured patients.

The nurse must be knowledgeable about any monitor used in a patient for whom they are caring. This includes understanding the purpose, limitations, and function of the device. The nurse needs to be able to interpret the numeric and any waveform data provided and appreciate the implications of these findings on functionality of the monitoring device and the care needed by the patient. To ensure that accurate measures are obtained, the nurse should properly level, zero, and/or calibrate the monitoring devices as needed according to the manufacturer's recommendations. Also the nurse should be well informed of any factors that may skew monitor accuracy or confound measures. When there is concern about the monitor's proper functioning and data accuracy, the nurse should be proficient in troubleshooting the device and know when to notify the provider about possible problems. Being well apprised of the desired therapeutic endpoints for any monitored parameters enables the nurse to guide nursing interventions and prescribed therapy to best reach preferred goals and to recognize when a provider-ordered change in treatment might be necessary.

Table 3. Techniques for brain monitoring

Technique	Detail	Advantages	Disadvantages
Neurologic examination	Global assessment of consciousness, sensory and motor responses, cranial nerve assessment, and ancillary tests	Can be used in all patients; findings can direct additional confirmatory testing or imaging	Affected by sedation, fever, seizures; in severely injured, exam may be static despite dynamic neurologic injury
Intracranial pressure (ICP) monitor	Typically monitored by a probe placed in the ventricle or parenchyma	Well established in traumatic brain injury; Ventricular drain allows removal of cerebrospinal fluid for ICP therapy/ labs; Enables cerebral perfusion pressure (CPP) calculation	Invasive monitor, potential risk for infection, hardware malfunction
Pressure reactivity index (PRx)	Algorithm relates changes in blood pressure to ICP to determine measure of autoregulation	Individualized measure of autoregulation and goal directed CPP therapy	Requires concurrent ICP monitor; an optimal CPP not always able to be calculated; software malfunction may occur
Cerebral microdialysis	Intraparenchymal probe obtains dialysate for lab assays	Informative of cerebral microenvironment and metabolic state; special lab assays possible	Invasive monitor, potential risk of infection, hardware malfunction; results potentially not reflective of entire brain
Jugular venous oxygen saturation (SjvO ₂)	Catheter placed in jugular bulb of internal jugular vein measures hemoglobin oxygen saturation	Allows for assessment of global cerebral oxygen supply and demand balance; guides therapy to promote adequate oxygen supply to meet metabolic need of the brain	Potential risk for infection, vascular injury or thrombosis; catheter malposition, damage or fibrin clot on the tip can cause inaccurate measures; regional brain ischemia may be underestimated or undetected especially in unmeasured hemisphere
Partial pressure of brain tissue oxygen (PbtO ₂)	Intraparenchymal probe measures partial pressure of oxygen	Enables targeted therapy	Invasive monitor, potential risk of infection, hardware malfunction; results potentially not reflective of regional oxygenation changes in other areas of the brain
Near-infrared spectroscopy/ diffuse correlation spectroscopy	Optical probes placed on the scalp. Measures cerebral oxygenation (NIS) and cerebral blood flow (DCS)	Noninvasive, cerebral oxygenation and extraction related to metabolism, cerebral blood flow, continuous monitoring possible	Assess brain tissue to a depth of 2-3 cm, typically frontal lobes
Continuous cerebral blood flow	Laser doppler flowmetry or thermal diffusion sensors placed on or in the brain cortex	Provide continuous measure of regional cerebral blood flow; allows for assessment of autoregulation	Invasive monitor, potential risk for infection, hardware malfunction; results potentially not reflective of other areas of the brain
Continuous electroencephalography	Assess brain electrical activity through scalp electrodes	Cerebral metabolic rate is related to brain activity; Can identify seizure activity	May be affected by sedation, intracranial mass lesions, presence of other intracranial monitors; inherently subjective interpretation; hardware malfunction; continuous monitoring not widely available
Serum markers	Measures of proteins indicative of neuronal injury	Non-invasive prognosticator of outcome	Not "real-time". Affected by extracranial trauma and timing of injury. Subject to differences in specimen handling, hemolysis and differences between laboratory assays

Nursing Interventions

Initial Resuscitation

Initial priorities in resuscitation of the trauma patient are to ensure a patent airway, sufficient ventilation, and control of hemorrhage with sufficient circulation [44]. These top three priorities are fitting for the trauma patient with brain injury since accomplishing these goals is essential to prevent hypoxia, hypercapnea, and hypotension – all key factors that can exacerbate secondary brain injury. Only after these concerns are addressed will attention focus on TBI-specific interventions.

Airway obstruction is not uncommon after TBI owing to the relaxation of the upper airway and backward prolapse of the tongue associated with unconsciousness, loss of protective airway reflexes (e.g., cough, gag), risk for vomiting and aspiration, and possible associated facial injury. Patients with TBI may have an associated spinal cord injury, and so consideration needs to be given to ensure spinal precautions when establishing the airway. Use of the chin lift or jaw thrust maneuver taking care to avoid neck extension is recommended to initially open the airway [44]. In the presence of obstruction or in patients with a GCS score ≤ 8 , endotracheal intubation is likely needed. The nurse can prepare the equipment and prescribed medications in anticipation of rapid sequence intubation and, if possible, obtain a neurologic examination before administration of these pharmacologic agents. Manual immobilization of the cervical spine and head should be maintained during intubation [44, 45]. If the provider is unable to secure an airway with an endotracheal tube, a surgical airway may need to be established. Once the tracheal tube is in place, the nurse should always make sure it is well secured to prevent inadvertent tube removal that could cause hypoxia and hypercapnea with devastating effects on neurologic outcome. Placement of an orogastric tube to decompress the stomach further assists in preventing aspiration.

Once the airway is established, ensuring adequate ventilation with sufficient respiratory gas exchange is important. The airway must remain clear, typically with endotracheal suctioning and in some cases a need for bronchoscopy. The nurse's careful assessment of the patient's breath sounds and respiratory pattern and effort helps to identify when the airway is congested and requires additional hygiene. The nurse and other members of the health care team should also assess for other associated life-threatening chest injuries (i.e., massive hemothorax, tension pneumothorax, open pneumothorax, flail chest with pulmonary contusion, cardiac tamponade) that require urgent intervention.

Continuous SpO₂ and ETCO₂ monitoring should be initiated to enable rapid recognition of deficient oxygenation and excessive or insufficient carbon dioxide. Typically, the desire is to keep the PaO₂ well above 60 mm Hg. In some institutions the PaO₂ goal is >70 mm Hg, and in others even higher thresholds are established. SpO₂ is usually targeted well above 90%, preferably $>94\%$. Supplemental oxygen is typically administered to achieve these oxygenation goals. When the patient has no evidence of brain herniation, the aim for carbon dioxide levels is the normal 35 – 45 mm Hg range [1]. It is important to avoid both hypocapnea, which causes cerebral vasoconstriction and possibly ischemia, and hypercapnea, which produces cerebral vasodilatation and may result in increased cerebral blood flow and intracranial hypertension [1].

In patients with severe TBI, ineffective respiratory patterns and medications that cause respiratory depression may contribute to insufficient ventilation [45]. Initially, manual use of

a bag valve mask at a rate that keeps ETCO_2 within the desired range can be employed, but mechanical ventilation is generally called for to support effective ventilation in this acute phase. The 4th edition of the Guidelines for Management of Severe TBI restate recommendations from the 3rd edition that hyperventilation should be avoided within 24 hours following TBI because of decreased cerebral blood flow at this time. Hyperventilation should be considered as a temporizing measure to reduce intracranial hypertension [1, 32].

Systemic hypotension in the trauma patient is likely from hemorrhage due to extracranial injury although medullary compression and impending brain death can also cause circulatory instability. Also associated cardiac dysrhythmias, myocardial dysfunction, pericardial tamponade or pneumothorax may cause hypotension and should be quickly corrected. Hemorrhage control and repletion of intravascular volume are important to regain hemodynamic stability. Generally isotonic crystalloids are infused and, if necessary, blood products to achieve euvoemia. Hypotonic solutions are avoided to prevent lowering intravascular osmolality, which can encourage fluid extravasation outside the blood vessels, thereby exacerbating cerebral edema. The patient's hemodynamic parameters and indicators of tissue perfusion (e.g., lactate, base excess) are used to guide fluid resuscitation so that excessive volume is not administered. Once euvoemia is achieved, use of vasoactive and inotropic agents may be prescribed to support the patient's cardiovascular status so that sufficient blood pressure and cerebral perfusion pressure is achieved.

As the airway, ventilation, and circulation are reestablished and cerebral perfusion and oxygenation are presumably better, level of consciousness may be noted to improve. Other etiologies for altered mental status may include drugs taken prior to or administered during hospitalization or hypoglycemia. It is important the patient's altered level of consciousness never be attributed solely to these or other conditions until brain injury is ruled out [44]. Timely clear communication to others on the resuscitation team about assessment findings is important so confounding factors that may impact the patient's neurologic condition are either ruled out or recognized and corrected.

A CT scan of the brain performed as soon as possible will assist in determining if there is brain injury and if so whether there is an urgent need for surgical intervention or indication for intracranial monitor placement. Extracranial injuries may also require immediate surgery, which may be done alone or together with any needed intracranial procedure. If indicated, the nurse quickly prepares the patient for operative intervention.

To ensure a thorough assessment, patients must be completely disrobed, which exposes them to the risk of hypothermia. Open wounds and administration of cold intravenous fluids add to the probability of lowered body temperature, which could increase the likelihood of coagulopathy and suppressed immune function [1]. While early prophylactic hypothermia has been suggested to be beneficial in lowering the cerebral metabolic rate, decreasing ICP, and reducing processes causing secondary brain injury, clinical trials have yielded conflicting results [1, 46–50]. The Guidelines for Management of Severe TBI provide only one recommendation (Level IIB) that states, in patients with diffuse brain injury, prophylactic hypothermia provided early, within the first 2.5 hours, for 48 hours post-injury is not recommended to improve outcomes [1]. Typically the goal is to maintain normothermia. It is important for the nurse to closely monitor the patient's temperature and use warmed blankets and intravenous fluids to prevent or treat hypothermia. In more severe cases, an automated blanket or endovascular temperature regulation device may be used to achieve normothermia. Hyperthermia, known to be a factor that aggravates secondary brain injury and worsens

patient outcomes, should be avoided, but should it occur, it demands prompt intervention to bring the temperature back to normal [3, 7, 12].

Nurses play an integral role in the resuscitation effort, working together with other members of the health care team to achieve the goals of initial resuscitation. Typically, during resuscitation each member of the health care team has clear responsibilities. Ongoing nurse assessment and vigilant monitoring of the patient helps identify areas of concern, evaluates the effect of interventions, and determines if the patient's condition is improving or deteriorating.

Nurses are responsible for implementing numerous prescribed and protocolized interventions, assisting the provider with procedures, and ensuring documentation of the care provided. Development of interdisciplinary protocols based on the best available evidence that clearly state desired therapeutic endpoints and interventions to achieve those goals can assist with decision making when monitored parameters fall outside the preferred range. Creation of provider order sets that include evidence-based best practices (e.g., deep vein thrombosis [DVT] and seizure prophylaxis) ensures important interventions are not inadvertently overlooked. These orders can also enable nurses to take specific actions when monitored parameters fall outside an acceptable range, ensuring a quick response to remedy the problem. The reader is referred to the chapter in this volume on Medical Management of Intracranial Hypertension and Indications for Secondary Decompressive Craniectomy for more detailed information on the medical management of patients with severe TBI.

It is important to treat pain and agitation to minimize cerebral metabolic rate, control possible intracranial hypertension, achieve patient comfort, and enable the patient to safely tolerate various diagnostic and therapeutic interventions. Analgesics and sedatives should be given with the knowledge that they will likely, at least temporarily, obscure the patient's clinical neurologic examination, hence the preferred use of short-acting or easily reversible agents such as fentanyl for pain or propofol for sedation. The nurse is responsible for administering these agents as prescribed and for pausing the medications when appropriate and as tolerated by the patient to obtain a neurologic examination. The nurse should always consider possible extracranial causes for agitation (e.g., hypoxia) that may require an intervention other than sedation to correct. Caution must be exercised whenever providing sedation or analgesia to a patient who is not supported on mechanical ventilation since any respiratory suppression could cause detrimental hypoxia and hypercapnea. Likewise, use of these agents can lower blood pressure, thus compromising CPP and increasing the likelihood of brain ischemia. Care should always be taken to avoid excessive administration of medication to prevent respiratory compromise or hypotension that may contribute to secondary brain injury and if noted they should be quickly corrected.

In addition, nurses offer information and support to the patient and family during this time of crisis. The patient may be unaware of or confused about his or her environment, and so the nurse should explain what is happening, reorient the patient frequently, and offer reassurance. It is likely the family will require repeated information about the patient's condition. When available, the assistance of pastoral care services and/or social work to assess and encourage use of effective coping mechanisms and supports can be helpful.

After initial resuscitation is complete, the patient with severe TBI is transferred to a critical care unit. The resuscitation nurse must provide a thorough handoff to the critical care nurse taking over the care of the patient. It is important that the transition report include the patient's assessment and changes that have occurred over time. It is ideal that the sending and

receiving nurses perform a neurologic assessment together to ensure there is good inter-rater reliability in how they are interpreting findings. Verification of the patient's identity and review of his/her history, mechanism of injury, diagnostic findings, infusions, tubes, drains, and family situation are important points to cover in the handoff report. Interventions that have been administered and the patient's response should also be reported, as well as any pending orders and the ongoing plan for care.

Ongoing Critical Care Management Prior to Decompressive Craniectomy

After initial resuscitation, the focus of care remains on prevention of secondary brain injury. Critical care nurses collaborate with others on the health care team to prevent, identify, and quickly intervene to remedy potential intracranial and extracranial complications associated with TBI. This requires nurses to provide frequent comprehensive clinical assessments while meticulously monitoring potentially numerous intracranial parameters as well as many measures that assess other body systems. All of these variables must be considered together with the desired therapeutic endpoints established for the patient when making treatment decisions. Again, institution protocols and order sets that define desired therapeutic endpoints and appropriate interventions are helpful in guiding clinical decisions about care. Daily multidisciplinary patient rounds and use of goals sheets that clarify individualized patient therapeutic goals each day can enhance effective communication and collaborative decision making with all members of the health care team.

Ensuring adequate respiratory gas exchange to prevent hypoxia or hypercapnea remains a priority. This can be challenging because of the prevalence of pulmonary complications, such as airway obstruction, atelectasis, pulmonary infection, pulmonary emboli, neurogenic pulmonary edema, and ARDS in patients with severe TBI. Both continuous monitoring of the patient's SpO₂ and ETCO₂ and regular assessment of respiratory status remain important so the nurse can readily detect hypoxia, hypercapnea, or evidence of pulmonary complications, thus allowing for prompt intervention to resolve these problems. Typically, the goals remain to maintain SpO₂ above 90%, preferably >94%, and the PaCO₂ in the normal range. When ICP becomes less responsive to initial interventions, the patient's PaCO₂ may be maintained more in the low normal range (35 – 38 mm Hg).

The nurse must continue to take precautions to ensure a patent airway. The endotracheal tube or tracheostomy tube must remain well secured, protected from inadvertent removal, and kept clear of secretions. Pulmonary hygiene, including suctioning and possibly chest physiotherapy, is important for secretion removal from the airway to prevent impediment to adequate respiratory gas exchange. These pulmonary hygiene interventions, while helpful in promoting airway patency, can raise ICP and compromise CPP and perhaps other monitored intracranial parameters [51, 52]. Use of evidence-based suctioning protocols for patients with severe TBI can be helpful to minimize any detrimental impact while employing this intervention [51–54] (see Table 4).

While performing these interventions, the nurse must carefully monitor the effect on the patient's neurologic function, including ICP, CPP, and when present other intracranial measures. Hygiene measure may need to be aborted if monitored parameters are sustained outside of the desired range. Pre-medicating the patient with a prescribed sedative and ensuring good body alignment may aid in the patient's ability to tolerate such pulmonary hygiene interventions [55]. It is important that the nurse keep the critical care and

neurosurgical teams informed of the patient's inability to tolerate these interventions so that this is considered when deciding on the plan for the patient's care.

Table 4. Research based recommendations for suctioning patients with traumatic brain injury. References [51 – 54]

- Pass the suction catheter for no longer than 10 seconds.
- Limit the catheter suction passes, preferably to no more than two passes per suction episode.
- Hyperoxygenation the patient before each passage of the suction catheter but avoid hyperventilation
- Minimize airway stimulation (i.e., stabilize the endotracheal tube; avoid passing the suction catheter all the way to the carina).
- Use of a closed suction catheter versus an open catheter may be preferable to minimize ICP elevations and PaO₂ reductions

Use of mechanical ventilation is likely in the critical care setting. The nurse needs to be aware of the effect that ventilator settings have not only on the patient's respiratory status but also on cerebrovascular status. As airway pressures rise, intrathoracic pressure can increase, thereby impeding cerebrovenous outflow and raising ICP. Venous return may also be impaired with high intrathoracic pressure possibly compromising blood pressure and cerebral perfusion pressure. Ventilation strategies that have been used effectively in other patient populations, such as permissive hypercapnea and use of high airway pressures in an attempt to recruit collapsed alveoli, will not likely be well tolerated in patients with severe TBI and poor intracranial compliance [45]. Both nurses and respiratory therapists need to remain cognizant of the impact mechanical ventilation settings have not only on respiratory measures but also on intracranial parameters and should notify the provider of any detrimental effect of mechanical ventilator setting changes.

Maintenance of an adequate blood pressure and myocardial performance to promote sufficient brain perfusion remains essential. A euvolemic state is desired and isotonic crystalloids remain the fluid typically administered. In patients at risk for high ICP, it is desirable to have a high normal or slightly increased serum sodium and osmolality so that fluid does not extravasate from the intravascular space and exacerbate brain edema. Red blood cells may be prescribed to treat anemia, and when a patient has undergone transfusion, the nurse should be alert for potential complications related to blood administration (e.g., transfusion reaction, transfusion related lung injury, transfusion associated circulatory overload). Other blood products (e.g., fresh frozen plasma, platelets, cryoprecipitates) and blood product derivatives (e.g., Factor VIIa, prothrombin complex concentrates) may be prescribed to prevent or correct coagulopathy commonly seen in patient with severe TBI [8, 9]. Failure to resolve coagulopathy can increase risk of intracranial bleed or re-bleed and is associated with higher mortality and unfavorable outcome following TBI [8, 9]. Patients' hemodynamic status, clinical assessment, and indicators of tissue perfusion help indicate when intravascular volume is sufficient. Vasoactive and inotropic agents are then titrated as prescribed to optimize cardiac performance and support an adequate blood pressure.

If other sources of hypotension or fluid and electrolyte imbalance are suspected, they should be investigated so the cause can be clarified and appropriate treatment to correct the imbalance can be initiated. Diuretic administration, surgical procedures, extracranial injuries,

diuresis from diabetes insipidus, and movement of fluid to the interstitial space due to inflammation can be sources of intravascular fluid loss. Hypertonic saline administration may also cause electrolyte and fluid disequilibrium. Water and sodium retention may result from stress-induced release of adrenocorticotrophic hormone (ACTH) and aldosterone, which causes antidiuretic hormone (ADH) release adding to water retention. Brain injury impacting the hypothalamic/ posterior pituitary system may result in insufficient ADH release causing neurogenic diabetes insipidus. Excessive ADH release, however, results in the syndrome of inappropriate ADH. Both of these ADH imbalances can cause substantial fluid and electrolyte alterations. Cerebral salt wasting, also triggered by brain injury, can cause salt and water loss, thus creating an imbalance. Acute adrenal insufficiency, which is present in a number of patients with TBI, can also lower blood pressure. Sedation and analgesic agents can pose a risk for hypotension and require careful blood pressure monitoring during and after administration. The risk of these imbalances and the threat they pose to the patient's hemodynamic and neurologic status reinforce the need for nurses to closely monitor intake and output, serum and, when ordered, urine electrolytes, and osmolality, as well as hemodynamic parameters and indicators of tissue perfusion.

Excessive hypertension could also prove detrimental due to venous engorgement and subsequent intracranial hypertension, although treatment is controversial. Some patients, such as those with brain ischemia, vasospasm, or history of chronic systemic hypertension, may benefit from a higher blood pressure. Brainstem compression can cause a compensatory elevation in blood pressure, so if the patient demonstrates other symptoms synonymous with this phenomenon, the nurse should immediately inform the provider so that interventions can address ICP reduction. If prescribed, antihypertensives should be administered with extreme caution so as to prevent detrimental systemic hypotension.

Prevention and management of intracranial hypertension is typically a focus in the critical care phase. When ICP exceeds the prescribed therapeutic threshold the nurse should ensure oxygenation, carbon dioxide levels, blood pressure, and fluid and electrolyte status are within the desired range. These therapeutic endpoints should be well communicated, and, as in the resuscitation phase, this is often best done with evidence-based protocols and order sets. Nurses caring for patients with severe TBI should be well educated on these protocols and seek clarification from the provider if unsure about the directions provided. In addition to ensuring sufficient respiratory gas exchange and desired fluid and electrolyte status, there are a number of nurse-driven interventions that may be effective in lowering ICP before resorting to additional medical or surgical interventions. These include patient positioning, maintaining normothermia, and employing patient care interventions as best tolerated by the patient.

Patient position can significantly affect ICP, CPP, and other intracranial parameters, as well as respiratory and hemodynamic measures. Evidence suggests a number of positioning techniques that can minimize ICP. It is important to maintain good head and neck alignment, avoiding head rotation and neck flexion or compression (e.g., from a cervical collar) to avoid impediment of cerebrovenous outflow, which increases intracranial volume and can elevate ICP [56, 57]. Avoid sharp hip flexion that may also aggravate increases in ICP. Altering the patient's position may cause a transient or sustained ICP elevation or may lower the ICP depending on the patient and position change selected. Turning should be done after first explaining the anticipated action to the individual and then gradually moving the patient while continuously monitoring the impact on intracranial, hemodynamic, and respiratory parameters. There are times when patients with intracranial hypertension and poor brain

compliance simply do not tolerate turning without having substantial ICP elevations, detrimental reductions in CPP, and/or perhaps adverse effect on other measured intracranial parameters.

In studies of patients with brain injury, a 30 degree head elevation yielded a lower ICP in most, a better or unchanged CPP, and no significant alterations in cerebral oxygenation versus when the head of the bed was flat [58]. When a number of head of bed positions were compared, the 30 degree elevation was optimal for controlling ICP and CPP in most subjects, but no single body position was identified that could reliably reduce ICP and increase CPP and brain oxygenation [59]. These results, together with findings from other studies of patients with severe TBI, suggest the head of bed position that best minimizes ICP and optimizes CPP and other cerebral parameters should be selected based on the patient's individualized response [59, 60].

Prone positioning has been advocated for improving oxygenation in patients with ARDS. A number of small studies exploring the effects of prone positioning in brain-injured patients with ARDS found that although ICP can increase with use of this position, CPP may remain sufficient and oxygenation improves [61, 62]. These findings suggest that the benefits of prone positioning may be achieved as long as cerebral parameters are closely monitored to detect unacceptable changes that warrant aborting this intervention. Prior to DC when ICP elevations may be refractory to initial interventions, prone positioning may not be well tolerated. The inability to provide this and other interventions to improve respiratory failure should be communicated to the critical care and neurosurgical providers so it is considered when deciding on escalation of treatment for intracranial hypertension.

In the patient with severe TBI, it remains important to maintain normothermia typically for the first 7 days after injury [63]. Ideally, a protocol and order set are established that prescribe appropriate interventions the nurse can use to reduce hyperthermia, which is prevalent after severe TBI. The nurse should continuously, or at least hourly, monitor the patient's temperature, but also note frequently the fluid temperature of any cooling blanket or endovascular catheter. If the temperature of the fluidized cooling system is dropping in an effort to maintain the patient's body temperature at normal, that suggests the patient may be trying to mount a fever or may be seizing or shivering. This provides indication for assessing other signs and symptoms of infection, including evaluation for the need to send cultures. Other extracranial etiologies of temperature elevation, such as blood or drug reaction, thromboembolism, or atelectasis, should be considered and treated appropriately. Seizures should be appropriately managed with prescribed anticonvulsants. Severity of shivering should be assessed and documented hourly by the nurse using the Bedside Shivering Assessment (BSA) scale [64]. Shivering may be less problematic when body temperature is reduced slowly and skin counterwarming (warming the face, hands, and feet to reduce the perception of cold) is used. When shivering exceeds a score of 0 on the BSA scale, additional anti-shivering interventions (e.g., buspirone, maintaining higher magnesium levels, additional sedation, analgesia, paralytics) are warranted and should be employed as ordered [65]. Failure to control shivering will make it difficult if not impossible to achieve and maintain normothermia.

The nurse must remain vigilant about the individualized effect that various stimuli (e.g., pain, familiar or unfamiliar voice, music) and nursing care interventions have on the patient. Nurses need to use sound judgment to determine the risk and benefits of each intervention. Nurses can anticipate that some care may not be well tolerated when brain compliance is low.

Poor brain compliance is suspected when the P2 segment of the ICP waveform is $\geq$ P1 or ICP elevations are sustained at rest or in response to interventions. Nyholm and colleagues [55] looked at brain compliance using amplitudes in the ICP curve (≥ 6 mm Hg), pressure autoregulation ($PRx \geq 0.3$), and baseline ICP ≥ 15 mm Hg as predictors of sustained ICP elevations (>20 mm Hg for 5 minutes or longer) associated with nursing interventions and found that baseline ICP ≥ 15 mm Hg was most important in determining risk of ICP elevations. When interventions that may cause ICP elevation or impose detrimental effects on other intracranial parameters must be carried out, the intervention should be well planned and done using a technique that minimizes adverse effects [55]. It can be determined if providing rest periods between activities or if providing added prescribed sedation or analgesia prior to performing interventions assists in helping the patient better tolerate the activity. Reducing unnecessary noxious stimuli and ensuring optimal patient positioning during the procedure also may foster tolerance of the interventions [55].

Sustained ICP elevations above the desired threshold together with a decline in the GCS score or pupillary changes call for prompt notification of the critical care and neurosurgery providers. A thorough assessment is needed to ensure all initial interventions remain in place and no other factor is taking place that could alter neurologic status or aggravate ICP elevation (e.g., hypercapnea, hypoxia, glycemic or electrolyte imbalance, infection, seizures). A repeat stat head CT scan is often prescribed and the nurse coordinates the needed members of the health care team for timely transport of the patient for the study. The nurse should assess the patient's ability to tolerate the flat position prior to leaving the unit and should anticipate the possible need for additional medical intervention (e.g., hyperosmolar therapy, sedative, analgesia) before lowering the head of the bed for the diagnostic test. When transporting the patient with an IVC, it is typically closed to avoid over drainage. Once in the procedural area if intracranial hypertension is a concern, the drainage system can be properly leveled, and if continuous drainage is prescribed, it can remain open for drainage during the procedure [66].

If an intraparenchymal ICP monitor is being employed and intracranial hypertension exceeds the therapeutic threshold, placement of an IVC may be considered. The IVC will provide the benefit of external ventricular drainage of CSF to treat elevated ICP. As described earlier, the nurse assists with the insertion and then manages the CSF drainage as prescribed.

Nurses are responsible for administering prescribed medical interventions to reduce or prevent intracranial hypertension. Details on these medical interventions are described in another chapter of this text on medical management of intracranial hypertension. Analgesia and sedation typically initiated in the resuscitation phase are generally continued in critical care to treat pain and agitation, thereby reducing ICP. A need for increased doses of sedative and analgesic agents is likely if intracranial hypertension persists. Nurses must anticipate that the neurologic examination will be obscured. It is important to watch intently for detrimental hypotension and other drug-specific complications that may be associated with administration of these agents. For example, when administering propofol, particularly at high doses (over 5 mg/kg/hour) or for prolonged periods (more than 48 hours), the nurse should closely monitor laboratory and physical assessment findings that may suggest onset of propofol infusion syndrome, such as elevated myoglobin, hyperkalemia, lipemia, metabolic acidosis, cardiac dysrhythmias, and evidence of renal or myocardial failure [1]. Early identification of these findings should be reported immediately so the propofol can be discontinued and another sedative selected.

Hyperosmolar therapy, another first-line intervention often used to control intracranial hypertension, entails administration of prescribed mannitol and/or hypertonic saline. Prior to administering mannitol, it is important to ensure the patient is adequately hydrated to reduce risk of systemic hypotension or renal failure that can result from use of this osmotic diuretic. Because mannitol can precipitate, a filtered needle should be used to administer the drug, preferably through a central line, to minimize risk of extravasation of this hypertonic solution into the tissues. Hypertonic saline may also be used instead of or in addition to mannitol. While 3% saline can be administered through a peripheral intravenous catheter, use of a central line for repeated doses is preferable. Central venous access should be used to infuse higher concentrations of hypertonic saline to avoid extravasation and subsequent tissue injury. Prior to hypertonic saline administration, hyponatremia, especially persistent hyponatremia, should be ruled out to avoid risk of causing osmotic myelinolysis. The nurse should remain vigilant for these and other potential complications associated with hypertonic saline use, including volume overload, hypernatremia, hemolysis, acid-base imbalance, and coagulopathies. Suggested use of sodium acetate rather than sodium chloride can minimize problems with metabolic acidosis. Use of either mannitol or hypertonic saline requires the nurse to closely monitor the patient's fluid and electrolyte balance, hemodynamic status, and effect on the patient's neurologic parameters.

Paralytics may be used in patients with TBI for rapid sequence intubation, to prevent movement so diagnostics and treatments can be safely performed, to control shivering associated with targeted temperature management, and to foster synchrony with mechanical ventilation. In some institutions, neuromuscular blocking agents are administered to stop movement (e.g., posturing) and reflexive responses to airway stimulation to control intracranial hypertension that requires treatment escalation. Early regular use of paralytics for ICP control was not found to improve overall outcomes and might prolong length of stay in the intensive care unit (ICU) and increase incidence of pneumonia and sepsis, therefore such use is typically not indicated [67]. When paralytics are used, the nurse should ensure adequate analgesia and sedation to block the perception of pain and control anxiety. The patient's neurological examination will be obscured except that pupil reaction typically remains present and should continue to be regularly assessed. Because movements associated with seizure activity will be concealed with paralytics, the nurse should be vigilant for unexplained elevations in heart rate, blood pressure, and ICP that may signal an underlying seizure that could be confirmed with an EEG.

The patient's individualized response and development of potential adverse reactions to each intervention should be noted by the nurse and communicated to the provider. Communication of persistent intracranial hypertension, detrimental alterations in other measured intracranial parameters, and/or inability of patient to tolerate potentially life-saving care (e.g., pulmonary hygiene) is essential for the health care team to make the best decisions on what additional interventions may be most appropriate. Intracranial hypertension refractory to initial interventions may be treated with an increased dose of sedation or added doses of hyperosmolar agents. Often multiple interventions are used together in an effort to reduce intracranial hypertension. Persistent intracranial hypertension despite initial interventions can lead to consideration of additional interventions more likely to have detrimental consequences, such as high dose sedatives, therapeutic hyperventilation, DC, high dose barbiturates, or hypothermia. The patient's condition as well as the risks and benefits of

each treatment option must be considered by the health care team when deciding on which option will be selected.

While preferably not used within the first 24 hours after injury when cerebral blood flow is decreased, hyperventilation may be selected as a temporizing measure to lower intracranial hypertension [1, 32]. When hyperventilation is used, the nurse needs to closely monitor the patient's ETCO_2 to avoid lengthy prophylactic reductions in $\text{PaCO}_2 \leq 25$ mm Hg [1]. It is recommended that a measure of cerebral oxygenation (e.g., jugular venous oxygen saturation, brain tissue partial pressure of oxygen) be monitored during use of hyperventilation so that inadequate cerebral oxygen delivery is quickly recognized and PaCO_2 levels can be appropriately adjusted [1, 32]. If hyperventilation is used, particularly when used for prolonged periods, the PaCO_2 should be gradually normalized to prevent a rebound increase in cerebral blood flow with a subsequent rise in ICP.

High dose barbiturates may be considered to treat intracranial hypertension refractory to conventional medical and surgical interventions in patients who are hemodynamically stable [1]. A loading dose followed by maintenance infusion is typically prescribed with the goal of controlling intracranial hypertension while ensuring sufficient CPP. The drug's effectiveness is considered optimized once there is burst suppression on the EEG. A number of detrimental side effects associated with high dose barbiturates can be life threatening to the patient and have significant implications for nursing care of the patient. Perhaps most worrisome is the myocardial depression and hypotension induced by the barbiturates that can cause an undesirable reduction in CPP and cerebral blood flow. Vigilant monitoring of the patient's hemodynamic status (e.g., continuous arterial blood pressure monitoring, cardiac output monitoring) is important to quickly recognize and act when hypotension or myocardial depression become evident. Vasoactive and inotropic agents may be needed to support cardiovascular function to ensure adequate brain perfusion. The patient's neurologic examination will be obscured, with many aspects of the assessment suppressed including level of consciousness, motor response, and many reflexes. Protection of the eyes is important to prevent corneal damage resulting from the suppression of the corneal reflex. Also, immunosuppression typically occurs and makes the patient vulnerable to infection, which may go unnoticed due to barbiturate-induced cardiovascular effects and lower body temperature. Gastrointestinal motility also may be reduced, which can affect the patient's ability to tolerate enteral nutrition.

Some institutions employ hypothermia to control refractory intracranial hypertension. Andrews and colleagues [68] conducted a randomized controlled trial in which adult TBI patients with ICP >20 mm Hg for 5 minutes without reversible cause were randomized to receive either standard care (the control group) or standard care plus hypothermia ($32^\circ\text{C} - 35^\circ\text{C}$ for at least 48 hours or until ICP was controlled) as a primary intervention. Recruitment for the study was halted due to safety concerns including more favorable outcomes, lower risk of death, and fewer adverse events seen in the control group. Despite these findings, others have suggested therapeutic hypothermia should still be considered for use in patients with refractory intracranial hypertension [69]. If hypothermia is used, the nurse needs to be well aware of its potential complications, including immunosuppression, fluid and electrolyte imbalance, coagulopathy, arrhythmias, hyperglycemia, and shivering, so that these adverse effects can be promptly recognized and treated appropriately. Shivering can be prevented and treated via prescribed anti-shivering interventions. It is important to ensure gradual rewarming.

DC is yet another intervention to be considered to treat refractory intracranial hypertension. Indications for DC, surgical technique, controversial aspects of this intervention, and potential complications are detailed elsewhere in this book. Once a decision to proceed with a DC has been made, the nurse makes preparations for the patient to go for the procedure. As time permits, this preparation includes ensuring the family has been informed about the procedure and its complications and has provided consent; administering any prescribed preoperative medications; halting any enteral feedings, removing any dentures, glasses, hearing aids, or prostheses; sending and checking results of prescribed lab work including a current blood type and cross match; making sure the ordered blood products are available; and verifying the appropriate patient and procedure. The nurse should provide a thorough handoff to the perioperative team ensuring the proper patient identity and reviewing the patient's history, all infusions, tubes, drains, monitored parameters, response to interventions, current assessment, and family contact information. The nurse and perioperative team coordinate preparation for transport and movement of the patient to the operating room.

When multimodal monitoring is used, other measured variables (see Table 3) in addition to ICP and CPP may influence clinical decisions about which interventions are selected to best manage the patient. Alterations in these additional intracranial parameters may precede changes in ICP and CPP, prompting diagnostic studies or specific interventions. For example, parameters that evaluate cerebral oxygenation may be helpful in decisions about ICP and CPP management, especially in selecting optimal CPP or guiding use of hyperventilation. Measures below the desired threshold may also prompt interventions that optimize oxygen delivery to the brain, focusing not only on optimizing CPP but also on the patient's oxygenation, respiratory function (e.g., ensure patent airway, pulmonary hygiene, and sufficient ventilation) and cardiovascular status (e.g., ensure adequate myocardial function, intravascular volume, blood pressure, and hemoglobin). Recognition and timely intervention to treat fever or seizures, which increase oxygen utilization, will be a priority to optimize cerebral oxygenation, reduce ICP, and prevent secondary injury.

Nurses must remain vigilant in preventing, recognizing, and treating a host of potential complications associated with severe TBI that can all trigger secondary brain injury. The neurologic injury, resulting deficits that occur, dysregulation of the coagulation system, injury-induced inflammatory response, or interventions used to manage TBI can instigate these complications. Astute ongoing assessment of the patient's clinical examination, monitored parameters, and diagnostic results allow for timely recognition of neurologic deterioration which may indicate delayed or expansion of cerebral hemorrhage, increased cerebral edema, or onset of posttraumatic hydrocephalus. These complications are often the triggers for intracranial hypertension.

Other worrisome potential neurologic complications include cerebral vasospasm, intracranial infection, and seizures. In the comatose patient, cerebral vasospasms can go undetected, but if suspected, a vascular study (transcranial Doppler, angiography) may be prescribed to diagnose or rule out this complication. Intracranial infection is more likely in those patients with open head injury or those requiring intracranial operative intervention or placement of invasive brain monitors. As previously noted, nurses play a vital role in ensuring strict sterile techniques are used during placement and manipulation of any intracranial monitor. The nurse also administers antibiotics prescribed prophylactically or for a known

infection. Attention to clinical evidence of infection or change in neurologic status by nurses is important so that timely intervention to treat this complication can be initiated.

Although the rate of clinical seizures after severe TBI is reported to be as much as 12%, the rate of subclinical seizures evident on EEG is double that at 20% to 25% [1]. Anticonvulsants that may have been initiated prophylactically for evidence of brain injury on the CT scan during resuscitation are generally continued for 7 days. The Guidelines for Management of Severe Traumatic Brain Injury recommend that when benefits outweigh the possible adverse effects of the drug, phenytoin should be administered to prevent seizures for the first 7 days (early seizures) after TBI [1]. While some institutions use levetiracetam for anticonvulsant prophylaxis, no evidence shows it is more efficacious than phenytoin [1, 70]. Administration of phenytoin starts with a loading dose followed by maintenance doses of the drug. Routine drug levels are generally prescribed to ensure the phenytoin levels are within the desired therapeutic range. All patients should have seizure precautions in place, and if a seizure occurs, the nurse should take note of the seizure characteristics and promptly notify the provider so that appropriate anticonvulsant therapy can be prescribed.

Not unlike the care of other critically ill patients, the nurse plays a vital role in preventing hospital-acquired infections in those with severe TBI. Risk of pulmonary infection is reduced by providing good mouth care; unless contraindicated, keeping the head of bed elevated at least 30 degrees; and preventing and routinely assessing for gastric distention [71]. Studies evaluating the effect of mouth care on ICP found clinically insignificant elevations occurred during the procedure and suggest oral hygiene is safe in patients with normal ICP. The effect in patients with intracranial hypertension requires further study [72]. Risk of central line associated bloodstream infections (CLABSI) is minimized by ensuring that best aseptic practices are used when inserting and maintaining central lines and that removal is timely. The Centers for Disease Control provides a Checklist for Prevention of Central Line Associated Blood Stream Infections that lists recommended best practices to prevent CLABSI [73]. Likewise, bladder catheter associated urinary tract infections (CAUTI) are avoided by inserting catheters using sterile technique and adhering to best practices for their maintenance and removal. A thorough review of evidence-based best practices for CAUTI prevention is described elsewhere [74].

Increased pressure within the abdominal cavity is transmitted to the thorax, which can then impede cerebral venous outflow and aggravate intracranial hypertension. Therefore, it is important for the nurse to routinely assess the patient for evidence of intra-abdominal hypertension and if suspected obtain intra-abdominal pressure measures. If intra-abdominal hypertension is present, decompressive laparotomy may be considered [75]. Placement of an indwelling bladder catheter and gastric tube for drainage typically done during resuscitation can reduce the distention that contributes to intra-abdominal hypertension. For more on this topic, the reader is referred to another chapter in this volume, Decompressive Laparotomy to Treat Intracranial Hypertension and Multiple Compartment Syndrome.

Patients with severe TBI generally become hypermetabolic, which can rapidly lead to protein-calorie malnutrition if nutrition is not initiated in a timely fashion. Ideally, collaboration with a dietitian to recommend needed nutritional support is helpful. The Guidelines for the Management of Severe Traumatic Brain Injury recommend providing nutrition so that the patient's basal caloric replacement is achieved by day 5 or day 7 at the latest to reduce mortality [1]. Nurses often have responsibility to place the enteral feeding tube and, once proper placement is confirmed, initiate prescribed feedings. A bowel regimen

should also be initiated to avoid constipation. The patient's tolerance of the nutritional support should also be evaluated and the provider notified if the feedings are not tolerated. Even before initiating feedings, the nurse should be closely monitoring glucose levels to avoid hyperglycemia and hypoglycemia, factors that can exacerbate secondary brain injury. Tight glucose control protocols may increase the risk of detrimental hypoglycemia. Therefore, treatment thresholds that maintain serum glucose >100 and <180 may be sufficient to prevent hyperglycemia and avoid low glucose levels [76].

Nurses must take action to reduce complications related to immobility caused by neurologic deficits as well as interventions (e.g., sedation, analgesics) used to treat TBI. Turning and range of motion should be attempted as tolerated. Patients who have poor brain compliance may not tolerate changes in position well. In this situation, a specialty bed or surface that reduces pressure is ideal for minimizing risk for a hospital-acquired pressure ulcer. Other pressure relieving measures (e.g., padded cervical collars, heel protectors) that protect bony prominences vulnerable to skin breakdown should also be used. Regular assessment of the skin, particularly under cooling pads and removable immobilization devices, is essential to identify any disruption in skin integrity.

Immobility as well as the hypercoagulable state following brain injury puts the patient at high risk for DVT. Pneumatic compression devices or compression stockings should be used. Pharmacologic anticoagulation (i.e., low molecular weight heparin or low dose unfractionated heparin) can be used together with the compression devices or stockings; however, because this risks further intracranial bleeding, it is not typically prescribed until the benefits outweigh the risk. The Guidelines for the Management of Severe Traumatic Brain Injury note that there is not ample evidence to recommend a preferred anticoagulant, dose, or timing of initiation for DVT prophylaxis [1]. In patients with refractory intracranial hypertension where DC is planned, pharmacologic prophylaxis will typically be held.

During this critical care phase when the patient's condition is tenuous, the patient's family will need frequent communication and support. When the family is present at the bedside, the nurse has an opportunity to use oral and written strategies, to explain what is happening with the patient and to teach them how to best interact with their loved one. Interdisciplinary family conferences where all providers and the family members meet to discuss the patient's plan of care offer an opportunity for the family to ask questions and participate in decision making. Social workers, pastoral care, and, when available, family navigators can be used as needed and desired by the family to provide much needed support [77].

POSTOPERATIVE NURSING CARE OF PATIENTS UNDERGOING DECOMPRESSIVE CRANIECTOMY

Postoperative interventions to maintain the desired therapeutic endpoints for patients with severe TBI after DC are very similar to preoperative interventions, which attempt to prevent secondary brain injury. Continued use of protocols and order sets based on the best available evidence to guide practice and clinical decision-making are helpful. Effective strategies to communicate the plan of care between practitioners remain essential in this postoperative

phase. The nurse remains a vital member of the health care team and a key coordinator for the complex care needed by patients and their family after DC.

Continued Close Assessment and Monitoring for Intracranial and Extracranial Complications

Postoperative nursing care of patients who have undergone DC continues to be extremely important, especially when considering the many serious potential complications of this procedure. These include wound break down, contralateral hygroma and hematomas, hydrocephalus, ipsilateral and interhemispheric subdural or subgaleal hygromas, seizures, cerebrospinal fluid leakage, hemorrhagic progression of contusions, persistent intracranial hypertension, brain herniation through small craniectomies, and subgaleal, superficial, and deep CNS infections [78]. Patients who have undergone DC are also at higher risk for injury related to compromised skull integrity. Honeybul and Kwok completed a retrospective analysis of 164 patients who required DC for severe head injury, during which 81 of those patients (55.5%) had at least one complication after surgery. These complications were often associated with prolonged stays in both hospitals and rehabilitation centers [79].

Development of a subdural or epidural hematoma on the opposite side of the craniectomy site (contralateral hematoma) is a serious complication after DC. A study by Su and colleagues found that patients with contralateral hematomas often present with postoperative pupillary abnormalities, acute neurological decline, and increased ICP that becomes unmanageable, causing severe consequences for the patient [80]. Hydrocephalus is a more frequent complication of DC following TBI and may lead to clinical decline and poor patient outcomes if not recognized and treated with therapeutic diversion of CSF to normalize ICP [81]. Subdural or subgaleal hygromas are other well-known complications of DC that result from collections of CSF. Aarabi and colleagues found, in 39 patients who developed a subdural hygroma (SDG) after DC and survived >30 days, that SDG was evident on CT scan during the first postoperative week. Volume of the SDG peaked at 3 to 4 weeks after DC and then gradually resolved around week 17 [82]. Approximately 2 months after injury, nearly 8% of the SDGs transformed into subdural hematomas [82]. According to Honeybul and Ho, patients with SDGs were more likely to have longer hospital stays and take more time in rehabilitation with poorer neurological outcomes at 18 months after surgery than patients without hygromas [83].

Due to concerns about post-DC complications, as well as the continued worry about exposure to factors that could exacerbate secondary brain injury, postoperative management routinely occurs initially in the ICU where ICP continues to be monitored. Nurses with astute assessment skills who are knowledgeable about signs and symptoms of possible complications have the potential to recognize these intracranial complications early, promptly notify the provider, and initiate interventions to thwart further secondary brain injury. This requires performing frequent and thorough neurological assessments. Attention should be given to fluctuations in neurological status, detection of personality changes, as well as neurologic changes associated with patient positioning [78]. Also important is the continued monitoring of CSF drainage, ICP, CPP, and any additional brain parameters. In monitoring ICP after DC, it is important to note that the waveform may be dampened and a higher threshold for intervention may be prescribed.

Hospital-acquired infections including postoperative surgical site infections (SSIs) are also considered serious complications that often result in higher costs of health care, longer hospital stay for patients, and increased morbidity and mortality [84]. In patients with brain injury, infection can also prompt fever and secondary brain injury causing worse neurologic outcome. In order to help prevent these infections, nurses should be knowledgeable about the evidence-based best practices for prevention and management of SSIs. Together with other members of the interdisciplinary health care team, nurses can lead performance improvement initiatives that ensure best practices are consistently implemented and SSIs are reduced, thereby optimizing patient outcomes after DC. A wide variety of guidelines are available to assist nurses in this endeavor, including the Department of Health's Care Bundle to Prevent Surgical Site Infection, SSI quality standards from the National Institute of Health and Care Excellence, and the World Health Organization's Surgical Safety Checklist [85]. These guidelines and checklists recommend specific interventions to be utilized by nurses and other members of the health care team, such as diligent hand hygiene, surveillance of SSIs, patient education, and wound care practices.

Aspiration frequently occurs in brain-injured patients because of neurologic impairment that causes disturbances in oral, pharyngeal, and esophageal functions, sometimes including loss of protective airway reflexes. Also, patients may have disruptions in cognitive function and behavioral processes that interfere with normal swallowing mechanisms [86]. Most patients who have undergone a DC have been subjected to prolonged intubation and mechanical ventilation, typically longer than 48 hours, which is also thought to contribute to swallowing dysfunction through factors such as alterations of glottic anatomy, atrophy of skeletal muscles of the larynx related to inactivity, and suppressed level of consciousness [87]. Swallowing dysfunction can lead to aspiration and aspiration pneumonia, which are preventable with proper nursing care.

Aspiration pneumonia is often associated with dysphagia and ineffective cough. Following brain injury the hypoxia, hypercapnea, and fever from respiratory infections can be particularly detrimental owing to their threat to exacerbate secondary brain injury. Mortality rates for aspiration pneumonia range from 20% to 65%, and diagnosis is often predictive of hospital readmissions [88]. These statistics clearly support the importance of nursing interventions to avoid aspiration and aspiration pneumonia. While the patient is intubated, nursing care continues to include keeping the head of the bed elevated 30 degrees or higher if not otherwise contraindicated, providing good mouth care, and implementing interventions to facilitate ventilator weaning and safe extubation of the patient [71]. A swallow evaluation should be completed prior to beginning oral intake of fluids or food. Hospitals have implemented various guidelines and dysphagia screening tools to help nurses adequately assess swallowing in specific patient populations, including those with altered mental status, seizures, and post-airway extubation. For example, the University of Maryland Medical System utilizes a Registered Nurse Dysphagia Screening Algorithm with specific interventions to assist nurses when screening these high-risk patients. Prior to a patient's oral intake of fluid, foods, or medications, nurses answer several yes or no questions to assess that person's alertness, breathing, coughing, speech, and voice quality. Once the questions are answered, nurses will either administer water and perform a bedside swallow evaluation, or notify the provider and request a formal swallow evaluation from speech-language pathology. The nursing bedside swallow screen involves administering small amounts of water while carefully observing the patient for signs of aspiration. Reportable conditions that are

considered signs of aspiration include respiratory distress, coughing, choking, throat clearing, or change in vocal quality either during or after the screening.

After DC, the patient is at high risk for secondary brain injury from any impact to the head where there is compromised skull bone integrity. Because a portion of the skull is removed, standard nursing care should involve fitting the patient for a protective helmet. The helmet helps to prevent additional brain injury from events like falls by providing padding over the skin and open cerebrum [78]. Single case reports have shown that a fall after DC can cause catastrophic consequences, which provides justification for the routine use of a cranial helmet during mobilization after craniectomy [89].

Progress to Recovery

Overall, patient outcomes after DC may vary significantly, but generally fall into the two separate categories of recovery or death. The term *recovery* is used broadly in view of the fact that some patients recover full function and may return to their previous level of independence (i.e., to school, work, and other prior responsibilities), while others suffer serious long-term cognitive and other neurologic deficits that forever impede their ability to live independently [90]. During recovery, nurses should assess patients for frequently reported physical, emotional, cognitive, sensory, or sleep symptoms that may be related to the brain injury itself, or may be caused by other factors such as anxiety, depression, chronic headaches, bodily pain, posttraumatic stress, psychosocial factors, or personality changes [91]. During the first few weeks up to several months after DC, it is important for nurses to carefully monitor patients and seek feedback from family to identify apparent personality changes or decreased level of consciousness that could indicate development of late-onset seizures, hydrocephalus, or syndrome of the trephined [78]. Syndrome of the trephined is a rare, but important complication of craniectomy, characterized by neurological dysfunction with varied symptoms including cognitive, motor, and language defects that improve after cranioplasty [92]. Nurses should coordinate care with the medical and neurosurgical teams to help identify the ideal timing for bone flap replacement.

Nurses should also monitor for other complications after cranioplasty including surgical site infection, discussed previously, and bone flap resorption. Bone flap resorption is reported in 2% to 32% of patients who have had a cranioplasty and results in cosmetic flaws, as well as increased risk of brain injury. This complication often requires further surgical interventions and replacement of the bone flap with other foreign materials [93].

Major depression is frequently recognized as a significant comorbid condition associated with TBI and is associated with adverse outcomes including lower quality of life, greater physical disability, poor psychosocial functioning and community participation, and suicidal ideation [94]. Evidence-based tools should be used to assess patients for the presence of depression, which DC patients are at high risk for developing [78]. The Patient Health Questionnaire 9 (PHQ-9) is one of the most widely used depression screening tools developed to assist providers in working with various types of clinical populations and settings. The questionnaire is brief and can be used to assess for the presence and severity of depression in the previous 2 weeks. Patients are asked a series of nine simple questions about feeling down or depressed, difficulty sleeping, eating habits, energy levels, ability to concentrate, level of

interest in doing things, and thoughts of suicide. Prior evidence has been gathered verifying the validity of using the PHQ-9 in patients with mild to severe TBI [95].

Cognitive Therapy

As previously mentioned, patients with brain injuries can suffer from long-term cognitive deficits that interfere with return to independent living. Cognitive therapy can help them gain more independence, with the possibility of returning to their prior living situations and responsibilities [90]. Patients with severe injuries are more difficult to treat because they suffer persistent adverse consequences that affect their general quality of life [96]. Therapy teams consist of physical, occupational, and speech language therapists (SLPs) who are responsible for evaluating and treating these patients once they are stabilized after surgery. Nurses should ensure consultations for these therapies are requested and then may coordinate timing of these evaluations. SLPs perform thorough initial cognitive assessments that are used to determine therapy needs and patient disposition after discharge from the hospital. This assessment is also used throughout the course of patients' recovery, either during inpatient rehabilitation or outpatient therapy. Many patients receive cognitive therapy from nurses or therapists who focus on improvement of attention, learning, and memory in hopes of an eventual safe return home. A literature review by Stephens et al. [97] identifies and summarizes evidence-based recommendations focused on cognitive rehabilitation for adult patients with brain injuries. These recommendations include promoting self-awareness, encouraging learning and memory, developing executive function, and improving overall cognitive function, also known as daily cognition [97].

Deficits in self-awareness and subjective well-being impair motivation to participate in therapy activities because the patient deems them unnecessary. Nurses and therapists can help the patient to first recognize their deficits, which eventually leads to improving them. Difficulty with learning and memory causes patients to experience encoding deficits and struggle with being active participants in their own recovery. Strategies to promote deeper memory encoding and facilitate learning include self-generation, which asks patients to create their own examples for understanding new material and spacing out information, which facilitates learning by providing small amounts of new information over relatively short periods of time. Deficit in executive functioning, which is the ability to plan, organize, strategize, and focus attention, can be profound and debilitating, and have the strongest effect on functional outcomes. Providers can improve deficits in executive functioning by encouraging patients to use metacognition, which is the ability to recognize their own cognitive capacity and seek other methods to enhance functioning. For instance, patients who have difficulty understanding and remembering orally presented information can use the metacognitive strategy of requesting written or other visual information, which nurses and therapists can utilize for learning assessments and patient education. Finally, the literature review examined methods to improve overall cognitive function, also known as daily cognition. These methods include using different forms of technology to assist patients with learning skills needed for daily functioning, as well as providing therapy in the patient's natural environment or a virtual reality environment, which supports the concept that relearning daily tasks in a natural setting leads to greater functional gains [97].

Preparation for Transition from Acute Care

Patients recovering from DC eventually transition from the acute care setting to inpatient rehabilitation centers or skilled nursing facilities, depending on their required level of care. In the past several years, enactment of the Affordable Care Act in the United States, reimbursement based on pay-for-performance models, and implementation of readmission penalties for preventable diagnoses have required health care organizations to focus more on transitional care, as well as care coordination. Following a brain injury and DC procedure, patients commonly require and receive follow-up treatment in various settings, including inpatient rehabilitation. Nurses have a responsibility to help these patients successfully transition from acute care to rehabilitation facilities, which also helps to prevent unplanned readmissions, increased health care costs, and other complications or medical errors. The appropriate type of discharge facility is decided upon by a multidisciplinary team of health care providers, including physicians, advanced practice registered nurses (APRNs), physical, occupational, and speech therapists, case managers, and social workers. Team members complete an array of diagnostic tests, assessments, and evaluations in order to determine the level of care and rehabilitation required by each patient. Patient needs, patient/family preference, and insurance coverage or payment methods then help determine the selection.

Nurses should strive for successful patient transitions from acute care to rehabilitation facilities by providing adequate patient and family education, promoting independence, assisting with and encouraging early mobilization, and ensuring patients are adequately prepared to participate in rehabilitation and cognitive therapy. Patients and families should have a complete understanding of the diagnosis and possible complications. Providing adequate patient and family education involves teaching about important safety issues such as fall prevention and the use of protective helmets, medications and possible side effects with medication changes, as well as, surgical site monitoring and interventions to prevent infections. They should be fully informed regarding follow-up needs, future appointments, and whom to contact with questions, concerns, or problems after discharge. Patient and family education is fundamental for successful outcomes after discharge. Clinical nurses play a vital role in the delivery of this education and have the unique opportunity to have an impact on these outcomes.

Nurses should also promote early independence, which better prepares patients for rehabilitation, where they relearn activities of daily living, including self-care tasks such as bathing/showering, toileting, personal hygiene and grooming, dressing, self-feeding, and functional mobility or transferring. Encouraging patients to independently perform these activities while in the acute care setting allows for better outcomes and shorter lengths of stay in rehabilitation facilities. The standard of care for DC patients in the ICU includes several days or even weeks of mechanical ventilation, which often includes deep sedation and prolonged immobility. Critically ill patients who are not mobilized during early phases of hospitalization experience deconditioning, persistent weakness, alterations in neuro-psychological function, and decreased quality of life. Once DC is performed and the patient's condition stabilizes enabling safe movement out of bed, early mobilization should be initiated. Early mobilization protocols used by nurses, who are key providers of mobility for these patients, can improve a number of patient outcomes including reduced duration of mechanical ventilation and overall length of stay in the ICU [98].

Finally, patients must be adequately prepared to participate in rehabilitation and cognitive therapy. Symptoms of brain injury may include agitation, hostility, anxiety, fatigability, and depressive mood, which can impede patients' ability to participate in these activities [99]. Because nurses spend the most time with patients, they can help other members of the interdisciplinary health care team determine whether patients are prepared for the transition from acute care to inpatient rehabilitation.

Brain Death

Unfortunately, not all patients recover, and some will suffer from refractory intracranial hypertension, cerebral ischemia, and eventually brain death. Brain death is considered irreversible and is defined by The American Association of Neurology (AAN) based on three cardinal signs: coma or unresponsiveness, apnea, and cessation of the functions of the brain including the brain stem [100]. Nurses are often present and may be required to assist physicians by monitoring the patient during clinical testing used to diagnose brain death. Nurses can help to ensure patients are normothermic, hemodynamically stable, and free from sedative and paralytic drugs when physicians are performing the brain death examinations. Coma is diagnosed when patients become unresponsive to deep central pain such as sternal rub or supraorbital pressure. Nurses also assist physicians to assess the cessation of brain functions during formal evaluations of brain stem reflexes (e.g., corneal reflex, pupil light reflex, gag, cough, oculovestibular reflex, and if the cervical spine is cleared, the occulocephalic reflex); these are clinical tests that must all be negative to diagnose brain death. Finally, an apnea test is done to determine there is no function of the brain stem respiratory center by verifying the patient has no spontaneous respirations when carbon dioxide levels are elevated [100].

After the diagnosis of brain death is made, nurses are responsible for patient monitoring, clinical management, and, most importantly, patient advocacy and family care. Many patients complete documentation that expresses their wishes regarding donation of their organs (e.g., advanced directives, organ donation registration), and nurses should help advocate for their patients' preferences. A 2013 article in *Critical Care Nurse* [101] highlighted several recommendations to assist nurses in providing family members with the best possible nursing care during this stressful and difficult time. Nurses are pivotal in establishing trust while helping the family to understand a continuous stream of complicated medical information from the interdisciplinary team of health care providers. The nurse is often able to reinforce information to provide the family with a better understanding of brain injury, as well as the progression of the injury to brain death. When formal brain death testing is completed, nurses should allow family members the time and opportunity to process their experience and express their emotions. Resources such as chaplains or other spiritual support that take into account the families' cultural and religious preferences can be very helpful in providing the family support. Religious issues are of extreme importance when discussing brain death with family members, and understanding these issues can better assist with the difficult discussion of organ donation. Finally, before discussing organ donation nurses should use consistent terminology and definitions to ensure the family understands brain death.

CONCLUSION

Nurses are essential members of the health care team striving to achieve optimal outcomes for patients with severe TBI before and after DC. Their role requires compassion, strong critical thinking skills, and a sound knowledge base. They have the responsibility to interpret clinical examination findings and monitored parameters to determine appropriate interventions. Nurses communicate vital information about the patient's condition and response to interventions to other health care colleagues, thereby promoting well-informed collaborative decision making. Participation in decisions about the plan of care demands nursing awareness of the desired therapeutic endpoints for the patient and the expected effects, potential complications, and implications of each medically prescribed and nursing intervention. Nurses use interventions effective in reducing secondary brain injury, preventing and treating complications, and enhancing psychosocial, emotional, and cognitive aspects of the patient before and after DC to realize optimal outcomes for patients and their families.

Chapter 228

DECOMPRESSIVE LAPAROTOMY TO TREAT INTRACRANIAL HYPERTENSION AND MULTIPLE COMPARTMENT SYNDROME

Margaret H. Lauerman*, MD and Thomas M. Scalea, MD

Department of Trauma/Critical Care, R. Adams Cowley Shock Trauma Center,
University of Maryland Medical Center, Baltimore, MD, US

ABSTRACT

Multiple compartment syndrome (MCS) encompasses the interconnected physiology between the abdominal cavity, thoracic cavity, and cranial vault. The cranial vault cannot be considered in isolation, and elevated pressure in one of these compartments can affect pressure in another compartment. Elevations in intra-abdominal pressure must especially be considered in patients with MCS since relief of elevated intracranial pressure (ICP) in MCS often requires decompressive laparotomy for its decrease in addition to the usual therapy aimed at lessening cerebral edema and intracranial hemorrhage. Without identification of MCS in patients with elevated ICP and decompressive laparotomy, elevation in ICP will persist.

Keywords: decompressive laparotomy, open abdomen, multiple compartment syndrome, intraabdominal pressure

INTRODUCTION

The brain does not exist in isolation but in fact interacts with other organs outside of the central nervous system (CNS). The cranial vault sits on top of a series of compartments that include the thorax and the abdomen. Pressures in one compartment can be transmitted to an

* Corresponding Author's Email: mlauerman@umm.edu.

adjacent compartment. For instance, intra-abdominal pressure (IAP) can be transmitted to the thorax and then even to the brain.

Therapies commonly used to reduce excessive pressure in extracranial compartments may then similarly affect the brain. Something as simple as a ventilator manipulation in acute respiratory failure or fluid resuscitation for hemorrhagic shock may have an unintended secondary effect on the brain by raising intracranial pressure (ICP). While therapies for elevations in ICP are generally intended to affect the brain directly, these relationships raise the possibility that ICP can be modulated by altering pressures outside of the cranial vault. Clinicians must have an intimate knowledge of these relationships in order to care for multiply injured patients with severe brain injury.

Principles of Compartment Syndrome

Compartment syndrome, defined as an elevation in pressure that decreases perfusion within a confined body cavity, is induced by a variety of causes including trauma, immobilization, rhabdomyolysis, thermal injuries, coagulopathy, and infection [1]. While compartment syndrome can develop in many different body compartments, it is most commonly thought of as taking place in the extremities. Within the extremities, compartment syndrome most often occurs in the lower extremities but can also occur in the hand, arm, foot, or gluteus. However, compartment syndrome can also take place outside of the extremities. Abdominal, thoracic, and ocular compartment syndromes are uncommon, but do happen [2-4].

The extremity compartments are surrounded by a fascial layer, which is a relatively inflexible tissue that does not easily stretch [1]. The abdominal cavity is similarly surrounded by fascia. Regardless of the cause, as the pressure within a compartment increases, the fascia does not allow compartmental volume to expand. Instead, the fascia restricts the compartment's volume, and swelling within the compartment increases pressure rather than volume. In addition to the physical constriction of the fascia, molecular mechanisms are thought to play a role in development of compartment syndrome, including hypoxemia, hypoglycemia, and sodium-potassium channel dysfunction [1].

Because presenting findings for compartment syndrome vary depending on the body cavity involved (Table 1), the physical examination is commonly used to screen for compartment syndrome. Depending on the affected body compartment, invasive testing is used to measure compartment pressures and diagnose compartment syndrome (Table 2). Early diagnosis of compartment syndrome is crucial in that time to decompression is associated with the return of neurologic and muscular function in the extremities [5]. The mainstay of therapy for compartment syndrome is fasciotomy to release the pressure in the affected compartment and restore perfusion, with fascial release performed emergently to prevent further physiologic decline and tissue necrosis. The same principles are relevant in compartment syndrome regardless of the location.

Table 1. Findings concerning for elevated compartment pressures in multiple compartment syndrome

Concerning Findings For Elevated Compartment Pressure in Multiple Compartment Syndrome
Thoracic Cavity High ventilator driving pressure High peak airway pressure Abdominal Cavity Abdominal distention Abdominal tenderness Tense abdominal exam Decreased urine output Hypotension Elevated peak airway pressures Cranial Vault Diminished Glasgow Coma Scale score Pupillary abnormality Neurologic deficit

Table 2. Methods of compartment pressure measurement

Modern Methods of Measuring Compartment Pressure
Extremity Stryker® needle Thoracic Cavity High peak airway pressure (Inferred to be elevated) High ventilator driving pressure (Inferred to be elevated) Abdominal Cavity Bladder pressure Cranial Vault Intraventricular catheter Subarachnoid bolt

As pressure in a compartment rises, it can quickly exceed venous pressure. With initial elevation in pressure within the compartment, arterial inflow is maintained but blood cannot exit the compartment because of the increases in the pressure within the compartment. As the compartment pressure continues to rise, it ultimately exceeds perfusion pressure, resulting in ischemia. Within the extremities, myonecrosis takes place. Within the abdomen, organ dysfunction happens first, followed by tissue infarction.

Elevated ICP can correctly be considered “brain compartment syndrome.” In patients with traumatic brain injury (TBI), cerebral edema or hemorrhage can increase the pressure within the cranial vault. The rigid skull, much like the fascia that surrounds many extra-CNS compartments, prevents expansion of the cranial vault volume and thus the ICP increases. These increased ICP levels can produce cerebral hypoperfusion, much as hypoperfusion occurs in extra-CNS compartments with increasing compartment pressures. Ultimately, the brain herniates.

ABDOMINAL COMPARTMENT SYNDROME

Diagnosis and Monitoring

The first screening tool for abdominal compartment syndrome (ACS) is a high-quality physical examination. The abdomen should be visually inspected, auscultated, and palpated. Because the normal abdomen should appear flat and non-distended, any abdominal distention or a tense appearance should raise concern for elevated IAP. A tender abdomen on palpation should raise a similar concern. Physical examination in obese patients or non-responsive patients can be difficult, which is likely one reason that physical exam has not been shown to be universally effective for diagnosing elevated IAP [6, 7]. While physical exam is a costless bedside screen for ACS, given its limitations it should not be the definitive test.

When concern exists for elevation in IAP, measurement is the next step. IAP measurement is done by indirectly measuring a bladder pressure, which transduces the IAP across the bladder wall [4]. Previous measurement techniques using rectal, uterine, inferior vena cava, and gastric pressures, while possible, are no longer commonly performed [8]. To perform a bladder pressure, 25 cc of sterile saline is instilled into the bladder through a Foley catheter [4, 9], with a pressure then transduced. The gauge should be set at the level of the pelvis. For ideal measurement of a bladder pressure, the patient should be supine and paralyzed to prevent patient abdominal wall tension causing false elevations in pressure. Bladder pressures, although not a direct measure of IAP, have been shown to correlate well with actual IAP when created with laparoscopic insufflation [10]. The bladder pressure is not just a one-time measurement, and in patients for whom ACS is a concern serial bladder pressure measurements can be performed.

Normal IAP usually ranges from 5 to 7 mm Hg in critically ill patients, with elevated IAP defined as an abdominal pressure greater than 12 mm Hg [4]. Elevated IAP is a common finding in critically ill patients in the intensive care unit (ICU), with 32% of ICU patients showing evidence of such. Given the common occurrence of elevated IAP in critically ill patients, discerning a pathologic elevation from a non-significant elevation in IAP can be difficult [11]. ACS has classically been defined as an IAP measurement greater than 20 mm Hg with evidence of organ dysfunction [4]. Common clinical symptoms of organ dysfunction in ACS include hypotension, renal dysfunction with oliguria, or elevation in peak airway ventilator pressures.

Physiology

ACS, with its multitude of physiologic causes, can be divided into primary, secondary, and tertiary ACS. Primary ACS is caused by an intra-abdominal pathology, such as acute pancreatitis, intra-abdominal hemorrhage, or mesenteric ischemia. Intra-abdominal pressure rises either directly from the intra-abdominal pathology, such as in bleeding, or from secondary inflammation. Secondary ACS is caused by an extra-abdominal pathology such as large volume resuscitation for sepsis [4]. While resuscitation is often required for extra-abdominal pathology, the resulting visceral edema, edema of the abdominal wall, and

retroperitoneal edema can combine to elevate IAP [12]. Tertiary ACS is recurrent ACS after initial treatment of the disorder, and can be seen with premature abdominal wall closure [13].

Oliguria is one of the common signs of organ dysfunction in ACS. This decrease in urine output often occurs despite ongoing resuscitation [13]. However, the exact mechanism of oliguria and renal failure with elevated IAP is unknown. Diminished renal arterial blood flow, increased renal venous resistance, and decreased cardiac output are all proposed mechanisms of oliguria in ACS, with decrease in renal blood flow seeming to occur in animal models when IAP is between 20 and 30 mm Hg [14-16]. Alterations in levels of aldosterone, cortisol, and adrenaline may also induce renal vasoconstriction [16].

Cardiac failure manifested as hypotension also occurs with ACS. This organ dysfunction in ACS is mediated through the cardiovascular system even with primary intra-abdominal pathology. Hypotension in ACS is likely caused by both decreased preload and increased afterload with increased levels of IAP [17, 18]. With these changes to preload and afterload, cardiac output decreases, and hypotension then occurs [13].

The third commonly seen organ dysfunction in ACS is elevation in peak airway pressures on the ventilator, indicating worsening pulmonary dysfunction and increased intrathoracic pressure (ITP). In patients with elevated IAP, the diaphragm is pushed upward from the abdominal cavity against the thoracic cavity. Total lung capacity is decreased with this upward compression of the diaphragm, and functional residual capacity decreases as well [13]. Pulmonary compliance decreases and the chest wall stiffens [19], both of which contribute to increased peak airway pressures.

If left untreated, ACS can progress to intestinal ischemia. Superior mesentery artery (SMA) flow is shown to decrease with IAP as low as 3 mm Hg, and is 65% of normal SMA flow at an IAP of 40 mm Hg [20, 21]. The mesenteric veins, which have lower wall strength than the mesenteric arteries, are similarly compressed by elevations in IAP, reducing venous outflow from the intestines and contributing to visceral edema. This obstruction can initiate a cycle of worsening IAP, whereby venous outflow obstruction causes visceral edema, which elevates IAP, which worsens the venous obstruction, and onward in a self-perpetuating cycle [22].

EFFECT OF INTRATHORACIC AND INTRA-ABDOMINAL PRESSURES ON INTRACRANIAL PRESSURE

Intrathoracic Pressure

ITP can influence ICP via multiple pathways, all of which are through the cardiovascular system. Elevated ITP may impair cranial vault venous outflow through the internal jugular veins into the mediastinum. Venous return from the cranial vault into the central circulation is driven by a differential in pressure between the cranial vault and mediastinum [23]. When ITP is elevated, the pressure differential between the cranial vault and thoracic cavity can decrease, which can subsequently lessen cranial venous outflow. The resulting increased venous volume within the cranial vault can elevate ICP (Figure 1).

Increases in ITP can decrease cardiac output, in turn decreasing cerebral arterial blood flow. This lowered cerebral blood flow causes a reactive cerebral arterial vasodilation, which

increases the volume of blood within the cerebral circulation despite the decrease in blood flow. With the increased volume of arterial blood within the cerebral vault, ICP can rise [23].

Figure 1. Relationship between elevated pressure in the thoracic cavity, abdominal cavity, and cranial vault in multiple compartment syndrome.

Multiple maneuvers in the care of patients with TBI assist with optimizing the gradient for venous outflow from the cranial vault as well, and must be undertaken in concert with minimizing ITP. Jugular venous obstruction should be avoided given the variations in anatomy of the venous outflow of the cranial vault [24]. Additionally, the patient's head should be in a straight-forward position, as venous outflow can similarly become obstructed if the head is turned [25]. Cervical collars should be well-fitting and without excess pressure, as should any ties securing endotracheal tubes or tracheostomy tubes.

In general, for patients with an isolated TBI, the ventilator can be set without increasing ITP. However, in patients with TBI and concurrent pulmonary pathology, such as acute respiratory distress syndrome or pneumonia, a high ITP may be required to treat the pulmonary pathology. A balancing of increased ITP to prevent hypoxemia or hypercarbia and minimizing of ITP in light of the TBI must be undertaken. While it is known that patients with TBI and acute lung injury have worse outcomes, the ideal ventilator management strategy is unknown [26].

Intra-Abdominal Pressure

Elevated IAP is also associated with elevation in ICP. In an animal model in which elevated IAP was created by directly infusing solution into the abdominal cavity, when IAP was increased, ICP significantly increased, and when the abdomen was decompressed by removing the infused fluid, the ICP decreased [27], demonstrating a direct relationship between IAP and ICP.

In humans this association between IAP and ICP is similar. When a 15-pound water bag was placed onto the abdomen of patients with TBI, a significant increase in both in ICP and IAP was seen. The increase in ICP occurred soon after the increase in IAP. Notably, the initial ICP did not influence the amount of ICP increase following the creation of elevated IAP [28].

DECOMPRESSIVE LAPAROTOMY FOR ELEVATED INTRA-ABDOMINAL AND INTRACRANIAL PRESSURES

The relationship between ICP and IAP has been known for some time. However, manipulating it for patient care is recent. The first person for whom we used decompressive laparotomy to treat elevated ICP was a police officer who was injured in a high speed motorcycle crash. After evacuation of a subdural hematoma, he developed refractory elevations of his ICP, up to 45 mm Hg despite maximal medical therapy. His abdomen was distended with an IAP of 25 mm Hg. While his IAP was not as markedly elevated, abdominal decompression seemed our last possible option. He responded beautifully, required little in the way of additional therapy for his ICP, and made a complete neurological recovery. Several weeks later, we had another patient who also responded to abdominal decompression. This soon became part of our armamentarium for difficult to control ICP.

The first series of seventeen patients undergoing this procedure was from our institution and was reported in 2004. In that series, reductions in ICP were seen following abdominal decompression [29]. Patients who sustained drops in central venous pressure seemed to have the best neurologic outcomes. Today, decompressive laparotomy remains an important tool to treat refractory intracranial hypertension, particularly in multiply injured patients with TBI. This is true regardless of whether they have abdominal trauma. Even in the absence of direct injury to the abdomen, resuscitation needs for extra-abdominal injuries often can raise IAP and secondarily raise ICP. In our opinion, practitioners of all specialties who care for these patients must be cognizant of these relationships and options for therapy.

Technique of Decompressive Laparotomy

Treatment of elevated IAP should proceed according to the World Society for Intra-abdominal Hypertension guidelines. Medical treatment options for elevated IAP include gastric decompression, rectal decompression, diuresis, drainage of abdominal fluid, increased sedation, and paralysis [4]. However, with the development of ACS in any patient, or in TBI

patients with elevated IAP and intractable elevation in ICP, decompressive laparotomy should be performed.

A decompressive laparotomy is usually performed in the operating room. Critically ill patients, however, may not tolerate transport to the operating room, and the decompressive laparotomy can be performed in the ICU with the operating room team brought to the bedside of selected patients. While bedside laparotomy is feasible and can be life-saving, mortality risk is very high [30, 31].

Patients undergoing decompressive laparotomy are most often in the supine position, which starkly contrasts with the head of bed elevation used in patients with TBI. Of particular concern are the large increases in ICP that can occur when patients with TBI are laid flat [32]. Still, laparotomy can be performed in patients with elevated ICP who do not tolerate lying flat by positioning the patient in the reverse Trendelenburg position.

To perform the decompressive laparotomy, a vertical midline incision is made down through all the abdominal wall layers from the xiphoid process superiorly to the pubis inferiorly. This allows for the widest possible opening of the abdominal cavity. Full incision of the abdominal wall releases the abdominal contents that were under pressure. When ACS is present, the abdominal viscera will often eviscerate beyond the level of the abdominal wall, and not be completely reducible back into the abdominal cavity. The surgeon should explore the abdominal cavity to evaluate for any primary abdominal causes of elevated IAP, though in MCS this elevation is often the result of fluid resuscitation and not a primary intra-abdominal cause.

Managing the Open Abdomen

After the initial decompressive laparotomy has been performed, the abdominal wall is not closed. Instead, all the layers of the abdominal wall are left open to minimize the chance of recurrence of the elevated IAP. The abdomen is then covered with a temporary negative pressure suction dressing. Either a proprietary suction dressing attached to a portable suction machine or a homemade abdominal dressing attached to a wall suction container can be used as temporary abdominal coverage. Both dressings will remove fluid from the abdominal cavity, keep the intra-abdominal contents sterile, and cover the viscera while the patient recovers in the ICU.

Patients who are being managed with an open abdomen after decompressive laparotomy should undergo re-exploration every 2 to 4 days, and at each exploration the patient should be evaluated for definitive closure of the abdominal wall. Closure of the abdominal wall is usually not attempted if the patient still has persistently elevated ICP to avoid recurrent ACS. At abdominal re-exploration, if the fascia can be approximated and the tidal volumes do not worsen, the abdominal wall is closed. Decreases in tidal volumes with fascial closure are an indication of recurrent elevation in IAP inducing elevation in ITP. If the fascia cannot be reapproximated, the dressing is replaced over the abdominal wall.

Fluid status management in patients with an open abdomen can be difficult. Fluid output from the open abdominal cavity can be multiple liters per day, especially in patients who have undergone a substantial fluid resuscitation. However, a negative fluid balance in patients with an open abdomen can aid abdominal wall closure by decreasing visceral edema and increasing abdominal wall mobility. Achieving a negative fluid balance can be difficult in

patients with TBI where intravascular volume depletion can cause hypotension and a subsequent decrease in cerebral blood flow.

In patients who are unable to undergo abdominal wall closure after decompressive laparotomy, the abdominal wall is left open. Granulation tissue is allowed to form over top of the viscera in lieu of abdominal wall closure. Often an absorbable mesh is placed above the viscera to provide coverage. Once the granulation tissue has formed, the patient can undergo split thickness skin grafting to cover the wound and provide a permanent coverage over the viscera. Abdominal wall reconstruction is performed a minimum of 6 months later.

Because decompressive laparotomy has many potential complications, it is performed only in patients with a diagnosis of ACS or elevated IAP and intractable ICP elevations. Given that the cause of elevated IAP in ACS is often visceral edema, many patients undergoing decompressive laparotomy do not ultimately achieve abdominal wall closure [29]. Inability to close the abdominal wall exposes the underlying stomach, small bowel, and large bowel to potential enterocutaneous fistula formation, and the patient to higher rates of renal dysfunction [33]. Patients managed with an open abdomen who do not undergo fascial closure are left with a planned ventral hernia, and face future procedures to repair this hernia in an elective fashion after the acute illness has resolved [34].

MULTIPLE COMPARTMENT SYNDROME IN TRAUMATIC BRAIN INJURY

Overview

MCS was first described in trauma patients when it was noted that severely injured patients with TBI often developed elevated IAP and/or elevated ITP at the same time as elevated ICP. They seemed to have simultaneously developed compartment syndrome in multiple places, hence the term MCS. In the ICU, these changes can be insidious and extreme vigilance is required to recognize MCS when it is first developing. Commonly, the sequence of events of MCS development is as follows. A patient requires increased ventilator support. As ITP increases, cardiac output falls along with blood pressure. Typically, fluid is used to support the cardiovascular system, which may increase interstitial edema in the lung, prompting more support from the ventilator, and may increase visceral edema. As respiratory function worsens and ventilator needs increase, the ability to do positional therapy often decreases. Increases in ITP produce increases in IAP. Increases in ICP are treated with increased sedation and/or hyperosmolar agents that may then decrease intravascular volume. This cycle progresses, then repeats, and produces MCS.

Both decompressive craniectomy and decompressive laparotomy can decrease ICP in patients with MCS, whether used alone or in sequence. After decompressive craniectomy, patients with MCS had an improvement in ICP to below 20 mm Hg, with an 18 mm Hg mean decrease in ICP with decompressive craniectomy. After decompressive laparotomy, patients with MCS also had a significant decrease in ICP of 9 mm Hg, again to levels less than 20 mm Hg. When used in sequence, the order of decompressive laparotomy and decompressive craniectomy did not significantly affect mean ICP [35]. Therefore, surgeons should perform the procedures in the order deemed clinically necessary for the individual patient.

Multiple risk factors are associated with MCS development, although the amount of fluid resuscitation is likely the inciting factor. Patients with MCS had a drastically higher fluid administration, with 23 liters more given over the initial 7 days of the hospitalization, than patients who did not develop MCS [35]. Often in patients with MCS, ascites and liver congestion were noted at the time of laparotomy, confirming the substantial degree of fluid resuscitation administered in patients with MCS [29]. More critically injured patients with higher Injury Severity Scores were also more likely to develop MCS [35].

Outcomes in patients with MCS are worse than in patients with an isolated TBI without MCS. Mortality is higher in patients with MCS than in patients only requiring decompressive craniectomy. Patients with MCS have a 12% higher mortality than patients with elevated ICP requiring decompressive craniectomy without concurrent elevation in IAP [35]. Overall survival rates in series of patients with MCS range from 58% to 65%, with younger age being the only predictor of survival in MCS [29, 35]. Length of stay for patients with MCS was unsurprisingly higher as well [35]. Given these worse outcomes in patients with MCS, fortunately the development of MCS is rare, with only 2% of patients with a TBI developing MCS [35].

However, these risk factors do not completely explain the pathophysiology of MCS given the anatomic separation between the cranial vault and the abdominal cavity, and the connection between ICP and IAP is more complex than just an association between ICP and IAP. The relationship is likely mediated through the thoracic cavity, which separates the cranial vault and abdominal cavity, and involves relationships between ICP and ITP, and between ITP and IAP, with these complex relationships comprising the physiology of MCS explained below.

Physiology of Multiple Compartment Syndrome

The abdomen and the cranial vault are separated by the thoracic cavity, and in view of the known association of both ITP and IAP with ICP, the effect of IAP on ICP is likely transmitted through the thoracic cavity. Multiple animal models have demonstrated an active association between elevated ICP, IAP, and ITP. In an animal model of cardiopulmonary resuscitation (CPR), chest compressions during CPR induced a rise in both ITP and ICP. With abdominal binding, the increase in ITP with CPR produced a larger increase in ICP. This is likely due to the preferential transmission of pressure into the cranial vault given the restriction of the abdominal cavity with the abdominal binder [36].

In another animal model where IAP was elevated by inflating an intra-abdominal balloon, both ITP and ICP increased. With this increase in IAP, significant increases in peak airway pressures and central venous pressures were also noted, as was a decrease in cardiac index. However, in this animal model of intra-abdominal balloon insufflation, when a sternotomy and a pleuropericardotomy were performed to release the thoracic cavity as well, the increase in ICP was no longer seen with increasing levels of IAP, although the significant increase in peak airway pressure and the significant decrease in cardiac index were maintained [37]. This animal model affirms that the thoracic compartment is the connection between elevated IAP and ICP in MCS.

In humans, relief of MCS has proved the relationship between ICP, ITP, and IAP. When patients with MCS underwent decompressive laparotomy, mean ventilator airway pressure

had a significant decrease after 24 hours and ICP also showed a significant reduction [29, 35], likely indicating that decompressive laparotomy had lowered IAP, ITP, and ICP.

CONCLUSION

The cranial vault does not exist in isolation, as demonstrated by the interplay between ICP, ITP, and IAP. Elevated ICP in patients with TBI mainly requires treatment aimed at reducing cerebral edema and intracranial contents, but in patients with MCS it may require treatment aimed at extra-CNS sources. Volume of fluid resuscitation likely plays a role in the development of MCS, and fluid resuscitation in patients with TBI should be judicious given the potential development of MCS yet balanced against the need to maintain cerebral perfusion and prevent secondary brain injury. All patients with elevated ICP should be screened for a concurrent elevation in IAP, as ICP management in patients with MCS will be unsuccessful without decompressive laparotomy.

The realization that injuries could affect physiology and different body compartments gave rise to the recognition of multiple compartment syndrome. In fact, multiply injured patients may develop compartment syndrome in more than one body cavity, either from the direct effects of injury, such as severe TBI and intra-abdominal hemorrhage, or from the therapy of those injuries, such as large volume resuscitation in a patient with severe TBI and elevated ICP.

Chapter 229

DECOMPRESSIVE CRANIECTOMY IN ISCHEMIC STROKE

***Matthew Jaffa*, DO, Carolyn A. Cronin, MD, PhD
and Barney J. Stern, MD***

Department of Neurology, University of Maryland School of Medicine,
Baltimore, MD, US

ABSTRACT

Few stroke syndromes have as high a risk of mortality or severe disability as does the “malignant” middle cerebral artery infarction seen in the setting of large artery occlusions. Malignant stroke syndromes are relatively rare; however, when present they are associated with a close to 80% mortality rate. The management of these patients is controversial and presents a major challenge for the neurologists, neurosurgeons, and neurointensivists caring for them. Many studies have assessed the benefits and risks of decompressive craniotomy versus optimal medical management, with the goal of improving not only survival but also survival with good functional outcomes. The conclusions of these studies remain mixed, and practice patterns vary widely. We review the landmark trials of decompressive surgery in ischemic stroke as well as the pooled analyses and those addressing quality of life to improve our understanding of this complicated syndrome in which the optimal management strategy may vary depending on a patient’s values and preferences.

Keywords: malignant stroke, decompressive craniotomy, large artery occlusion, quality of life, functional outcomes

INTRODUCTION

Stroke is defined as the sudden onset of neurologic disability caused by neuronal death due to blockage or severely reduced blood flow or hemorrhage within the brain parenchyma.

* Corresponding Author’s Email: matthewjaffa@umm.edu.

Currently, stroke is the world's second leading cause of mortality and third for disability [1]. In the United States, stroke is now the fifth leading cause of death, is one of the top causes of long-term disability, and costs the nation nearly 33 billion dollars annually [1]. Larger territories of parenchymal damage typically equate to higher levels of morbidity and mortality. In this chapter we discuss the definition of malignant cerebral infarction and the role of decompressive craniectomy in the treatment of stroke and prevention of both morbidity and mortality.

In the United States, more than 80% of strokes are ischemic. Ischemic infarctions result from three main mechanisms: thrombosis, embolism, and cerebral hypoperfusion. Thrombosis typically is the result of disease of the arterial wall such as atherosclerotic plaque, whereas embolism is the result of vessel occlusion by blood clot or other material dislodged from a more proximal site such as a larger diameter vessel or a chamber of the heart. Thrombosis and embolism may lead to occlusion of vessels anywhere from the more proximal internal carotid artery (ICA) to the most distal branches of the intracerebral vasculature. Branches of the middle cerebral artery (MCA) are denoted with a number for each more distal branching point from M1 to M4. Each succession of branching vessels leads ultimately to an individual area of brain tissue perfused by the most distal vessels. Therefore, the more proximal a site of blockage is, the greater the amount of the parenchyma at risk for infarction. Systemic hypotension can lead to a more global process of damage with the greatest source of ischemic damage being in the areas of distal vessel overlap known as the "watershed zones" or "border zones" between the anterior cerebral artery (ACA), MCA, and posterior cerebral artery (PCA).

While a strategically placed stroke in the cerebral hemispheres or brainstem may lead to profound neurologic disability including loss of language abilities, alteration in personality, visual loss, and hemiplegia, few infarctions are associated with as high a likelihood of mortality or severe morbidity as are large artery occlusions that result in an infarction involving a large volume of brain. The "malignant" MCA syndrome is one of these infarctions, and typically is the result of occlusion of the distal ICA or proximal MCA [2]. Hacke introduced the term "malignant MCA syndrome" in 1996. It describes the small subset of stroke victims with severe hemiparesis and sensory loss, horizontal gaze deviation, and global aphasia (when the dominant hemisphere is involved) that progress to deterioration of their mental and respiratory status within the first 24 to 48 hours of symptom onset [2-5]. Death from cerebral edema and herniation leading to compression of the brainstem commonly occurs in the first 2 to 5 days following infarction [2, 3]. The malignant MCA syndrome is associated with a greater than 80% mortality [2, 6]. Fortunately, these infarctions are relatively rare, encountered in only about 10% of all patients with ischemic strokes [4]. Each year approximately 70,000 patients are at risk for the malignant MCA syndrome in the United States alone.

Predicting which patients will develop such severe stroke syndromes and their impending rates of death and disability is a source of great interest. Higher National Institutes of Health Stroke Scale (NIHSS) scores have a high sensitivity (96%) but a low specificity (72%) for those patients with scores greater than 19 in the prediction of the development of malignant stroke syndromes, while identification on magnetic resonance angiography of an internal carotid artery "T-lesion" has a lower sensitivity of 64% but greater specificity of 85%, making neither a perfect predictor [7]. Imaging findings have been found to have the strongest predictive value. Early work by von Kummer et al. showed that early computed

tomography (CT) hypodensity representing greater than 50% of the MCA territory within 5 hours of stroke onset was predictive of fatal outcomes in 85% of cases [8]. Later magnetic resonance imaging studies showed a 100% sensitivity and 94% specificity for predicting malignant MCA syndrome in patients with a diffusion-weighted imaging lesion greater than 145 mL up to 14 hours after symptom onset [3, 9]. Thomalla et al. demonstrated that more rapid completion of magnetic resonance imaging within 6 hours could be predictive of malignant MCA syndrome with changes in apparent diffusion coefficient volume greater than 82 mL [3, 7].

ACUTE MANAGEMENT OF ISCHEMIC STROKE

Time is of the essence in the acute management of ischemic infarction. Longer duration of ischemia leads to increasing neuronal death and likelihood of permanent damage. Treatment with intravenous tissue plasminogen activator (IV tPA) within 3 hours from the time of symptom onset has been shown to reduce morbidity at 3 months compared to placebo in the National Institute of Neurological Disorders and Stroke (NINDS) trial and then later with an extension of the time frame to 4.5 hours in the European Cooperative Acute Stroke Study 3 (ECASS III) [10, 11]. Data consistently demonstrate that for every 15-minute shortening in time to treatment there is a mortality and morbidity benefit [12]. The time standard of care for reperfusion treatment has been expanding since the positive results of trials for endovascular therapy were published beginning with the Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) [13] in January 2015. With the completion of additional trials, namely, Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE) [14], Extending the Time for Thrombolysis in Emergency Neurological Deficits - Intra-Arterial (EXTEND-IA) [15], Solitaire with the Intention for Thrombectomy as Primary Endovascular Treatment (SWIFT-PRIME) [16], and Randomized Trial of Revascularization with Solitaire FR Device versus Best Medical Therapy in the Treatment of Acute Stroke Due to Anterior Circulation Large Vessel Occlusion Presenting within Eight Hours of Symptom Onset (REVASCAT) [17], the American Heart Association/American Stroke Association (AHA/ASA) updated its acute stroke management guidelines to include use of endovascular therapy with stent retrievers for large artery occlusions (i.e., ICA and M1) for patients up to 6 hours from their last known normal time [18].

Ultimately, the goal of these interventions is recanalization of the occluded vessel to restore blood flow to distal ischemic tissue. Rha and Savers' meta-analysis of 53 studies examining recanalization reported that recanalization was achieved 24.1% of the time spontaneously, 46.2% with IV tPA, and 83.6% with mechanical thrombectomy [19]. Recanalization is determined by several factors, the most important of which are length and location of the thrombus. In MCA thrombosis there is a high likelihood of recanalization following IV tPA for clots less than 5 mm in length as compared to a less than 1% chance for clots longer than 8 mm [20]. Recanalization of the ICA has the lowest success rate at 49% across all methodologies, with IV thrombolysis yielding the lowest rate of 13% [19]. Even with the success of early recanalization, studies have shown that the final infarct volume, not

recanalization, is what drives outcomes [21, 22]. Thus, mitigation of the morbidity and mortality associated with these infarctions depends not only on recanalization success but also on the subsequent management of patients at high risk for malignant cerebral infarctions.

STUDIES OF DECOMPRESSIVE CRANIECTOMY

After the emergent management and stabilization of acute stroke patients, including patients treated with IV tPA or endovascular recanalization, the patient is typically observed in a critical care or stroke unit. Patients thought to be at risk for development of the malignant MCA syndrome are usually observed in a critical care unit.

The studies discussed here were all designed to answer the question of the role of decompressive craniectomy in the treatment of malignant cerebral edema following ischemic infarction. Trials looked at the outcomes of mortality as well as modified Rankin Scale (mRS) scores [23] to quantify long-term disability, as described in Table 1. On this non-linear scale, 0 indicates no symptoms while 6 indicates death. The differences between scores of 3 and 4 are related to the ability to ambulate and attend to one's bodily needs without assistance. These scores, which were found to have a significant relationship with discharge to institutional care in the large Nationwide Inpatient Sample data pool, are an active area of debate and discussion about how to judge the impact of the intervention [24, 25]. All trials were stopped early because of poor/slow enrollment and the desire to pool data for meta-analyses. These three trials form the basis of all the meta-analyses that will be reviewed later.

Table 1. Modified Rankin Scale scoring description

Modified Rankin Scale (MRS)	
0	No symptoms
1	No significant disability, despite symptoms; able to perform all usual duties and activities
2	Slight disability; unable to perform all previous activities but able to look after own affairs without assistance
3	Moderate disability; requires some help, but able to walk without assistance
4	Moderately severe disability; unable to walk without assistance and unable to attend to own bodily needs without assistance
5	Severe disability; bedridden, incontinent, and requires constant nursing care and attention
6	Death

DECIMAL [26]

The decompressive craniectomy in malignant MCA infarction (DECIMAL) trial was completed at 13 stroke centers in France from December 2001 through November 2005. The trial enrolled patients between the ages of 18 and 55 within 24 hours of an acute ischemic stroke that met criteria suggestive of the patient's being at high risk for a malignant MCA

syndrome. Patients were enrolled if they had an NIHSS score of greater than 16, CT of the head with hypodensity in more than 50% of the MCA territory, and a DWI stroke volume of greater than 145 mL. Thirty-eight patients were enrolled and randomized to receive either decompressive craniectomy within 6 hours of randomization or 30 hours following symptom onset versus maximal medical therapy which included preventing hyperthermia or hyperglycemia, maintaining the head of the bed to an elevation greater than 30°, intravenous hydration, and the use of intravenous mannitol in patients with rapidly progressing symptoms due to edema.

The results of this first study demonstrated a life-saving effect with respect to craniectomy. Those in the surgical arm had an almost 53% absolute reduction in death. Follow-up for patients was reported at 6 months and 1 year after enrollment. At both time points, a greater proportion of patients had a mRS of less than or equal to 3 in the surgical treatment group than the medical group. At 6 months the difference was 25% versus 5.6%, and at 1 year those percentages increased to 50% and 22.2% for surgical and medical therapy, respectively, as depicted in Figure 1; the P values for these data points were not statistically significant. When using mRS of less than or equal to 4 as the outcome measure, the difference at 1 year increased to 75% in the surgical arm versus 22.2% for the medical arm ($P = 0.0029$).

Figure 1. DECIMAL trial patient outcomes (Reprinted from *Stroke*, 38(9), Vahedi et al. Sequential-design, multicenter, randomized, controlled trial of early decompressive craniectomy in malignant middle cerebral artery infarction (DECIMAL Trial), Pg 2511, 2007, with permission from Elsevier).

The DECIMAL trial brought to light the idea that while survival was significantly improved by surgical intervention, the two treatment arms had no statistically significant difference in survivors with good outcomes (mRS less than or equal to 3). However, because the trial was stopped early, it likely did not have power to show a statistically significant difference.

DESTINY [27]

This trial of decompressive surgery for the treatment of malignant infarction in the MCA territory enrolled 32 patients across six study sites in Germany from February 2004 through October 2005. Inclusion criteria for this study included subjects aged 18–60 years, NIHSS score >18 in patients with non-dominant hemisphere infarcts and >20 when in the dominant

hemisphere, and CT imaging findings demonstrating infarction of greater than two thirds of the MCA territory including part of the basal ganglia. Patients were randomized either to conservative therapy, which allowed for the use of osmotic therapy for any signs of increasing edema, intubation and hyperventilation, sedation, ICP monitoring, and maintenance of normothermia and euglycemia, or to surgical decompression within 36 hours of symptom onset.

Randomization groups were fairly evenly matched, though it was noted that because of more patients with dominant hemisphere strokes in the control group, the NIHSS score was modestly higher at time of entry to the study in this group. Patients were predominantly screened and treated at one center. End points for the study included the 30-day survival reported as 88% in the surgical arm versus 47% in the conservatively managed group. The trial was designed to evaluate not only the mortality associated with malignant infarctions but also the functional outcomes at 6 months and 1 year, as represented in Figure 2. Again, the study results were dichotomized at a mRS score of less than or equal to 3, with 47% of patients achieving this in the surgical group and only 27% in those conservatively managed. These results again trended positive but were not statistically significant, whereas when the good outcomes score is expanded to mRS less than or equal to 4 there is a significant improvement based on surgical intervention.

Figure 2. DESTINY trial patient outcomes (Reprinted from Stroke, 38(9), Juttler et al. Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery (DESTINY): a randomized, controlled trial, Pg 2523, 2007, with permission from Elsevier).

HAMLET [24, 28]

The Hemicraniectomy After MCA infarction with Life threatening Edema Trial (HAMLET) was completed at six centers in the Netherlands from November 2002 through October of 2007 and enrolled 64 patients. Patients aged 18 to 60 years were randomized to surgical decompression or medical therapy within 96 hours of symptom onset. The inclusion time of up to 96 hours from symptom onset was a major difference between HAMLET and the other trials (24 hours for DECIMAL and 36 hours for DESTINY). Inclusion criteria included a NIHSS score of >16 in right hemispheric stroke patients and >21 for left hemispheric stroke patients as well as hypodensity covering at least two thirds of the MCA territory on CT imaging.

Figure 3. HAMLET trial patient outcomes (1 year) (Reprinted from *The Lancet*, 8(4), Hofmeijer et al. Surgical decompression for space-occupying cerebral infarction (the Hemicraniectomy After Middle Cerebral Artery infarction with Life-threatening Edema Trial [HAMLET]): a multicentre, open, randomised trial, Pg 329, 2009, with permission from Elsevier).

In this study, the only endpoint that was shown to have a significant reduction with hemicraniectomy was the likelihood of death, with an absolute risk reduction of 38%. The primary outcome of mRS dichotomized between 0–3 and 4–6 at 1 year had an absolute risk reduction (ARR) of 0%, though when extended to 0–4 versus 5–6 there was a trend toward benefit with surgical decompression and an ARR of 19%, as depicted in Figure 3.

Meta-Analyses

DECIMAL and DESTINY were halted prematurely in 2006 to combine the data for a meta-analysis. Each of the three trials had a similar protocol and outcome parameters allowing for relative ease of pooling patient data. Given the differences in eligibility criteria between studies, subjects were only included in the combined analysis with ages between 18 and 60, an NIHSS score >15, and a CT scan demonstrating infarction of at least 50% of the MCA territory or DWI infarct volume >145 mL. From these three studies, 93 patients were included who had been randomized within 45 hours of symptom onset [29]. In this data set, a primary outcome of mRS 0–4 was chosen to define favorable outcome, with secondary analyses using mortality at 1 year and favorable outcome of mRS 0–3.

The pooled analysis demonstrated the positive effects of decompressive craniectomy with an ARR of 51.2% when comparing patients with mRS 0–4 versus 5–6 at 12 months [29]. Craniectomy reduced rates of death from 71% to 21.5%, as seen in Figure 4, essentially inverting the historical mortality rate for malignant MCA infarctions. In addition, when

dichotomized for mRS 0–3 versus 4–6 there was still a significant ARR of 22.7% ($P = 0.014$). These data suggested that the previous concern that decompressive craniectomy improves survival while leaving the majority of patients in a severely debilitated state (i.e., mRS = 5) was false and that, in fact, the likelihood of this was nearly unchanged.

Figure 4. Pooled Analysis of DECIMAL, DESTINY, and HAMLET (1 year patient outcomes) (Reprinted from *The Lancet*, 6(3), Vahedi et al. Early decompressive surgery in malignant infarction of the middle cerebral artery: a pooled analysis of three randomised controlled trials, Pg 218, 2007, with permission from Elsevier).

In the years since this first meta-analysis and the results of the individual trials were published (2007–2009), several additional groups have looked at the data for hemicraniectomy in malignant cerebral edema related to MCA infarction. These studies again highlight the long debated question of the utility of surgical treatment in malignant stroke when the risk of severe disability is weighed against death and how severe disability should be defined.

Back et al. reviewed six studies in 2015 that included the three previously described studies as well as three more recently completed studies [30]. DESTINY2 [31], the follow-up to DESTINY, examined the effect of surgical decompression in patients older than 61 years. The Hemicraniectomy and Durotomy Upon Deterioration From Infarction-Related Swelling Trial (HeADDFIRST) [32] standardized the medical therapy provided to patients in neurologic intensive care units, including waiting until clinical deterioration before proceeding to decompression. Zhao et al. studied patients randomized up to the age of 80 in China [33]. To compare the 317 patients from these six studies, the researchers utilized odds ratios (OR) to assess the likelihood of each individual mRS outcome with respect to medical management versus surgery. They found that, as in each individual study, an mRS of 6 (death) was significantly reduced with surgical decompression with an OR = 0.19 and 0.17 at 6 and 12 months, respectively [30]. While the number of patients with mRS scores of 3 and 5 were increased at 6 and 12 months in the patients randomized to surgery, these did not reach statistical significance. The authors did find a significant increase in patients with mRS of 2 at 12 months (OR = 4.51). However, at both follow-up time points, surgical patients also had a statistically significantly higher likelihood of having an mRS of 4 with OR = 3.29 and 4.43 for 6 and 12 months, respectively [30].

Table 2. Likelihood of different outcomes based on meta-analysis of 6 trials [35]

	All patients		Patients >60 years	
	ARI	NNT	ARI	NNT
Excellent Functional Outcome (mRS 0-2)	6.6%	15.2	*	n/a
Favorable Outcome (mRS 0-3)	15.0%	6.7	4.0%	25.0
Unfavorable Functional Outcome (mRS 4-5)	29.5%	3.4	32.5%	3.1
*No patients > 60 with mRS 0-2				

ARI = Absolute Risk Increase; NNT = Number Needed to Treat.

Two additional meta-analyses have been performed by Yang et al. and Streib et al. utilizing five of the same six studies, but replacing the HeADDFIRST data with that from the preliminary results of a Croatian study by Slezins et al. [34, 35]. In the review by Yang et al. mortality was significantly decreased in the setting of early craniectomy (OR = 0.19, 95% confidence interval [CI]: 0.12–0.30; $P < 0.00001$), though the number of patients surviving with an mRS outcome of 4–5 was not statistically different for craniectomy or best medical therapy (pooled OR = 1.71, 95% CI: 0.78–3.74; $P = 0.18$) [34]. Both demonstrated that regardless of age the results were consistent, although in patients older than age 60 the likelihood of achieving survival with an mRS of less than 3 was zero regardless of treatment arm, and only 7% had a score of 3 after surgery compared to 3% in the medical arm [35]. In their primary analysis, Streib et al.'s meta-analysis evaluated the absolute risk increase for undergoing early craniectomy and therefore number needed to treat to meet defined functional outcome categories. Table 2 shows likely outcomes based on data from Streib et al. [35].

More recently, Dasenbrock et al. analyzed data from the National Inpatient Sample database to assess the predictors and association of time to decompressive craniectomy with outcomes. The review of approximately 1300 inpatient admissions evaluated the outcomes of discharge to institutional care (i.e., nursing facility, extended care facility, or hospice, but excluding rehabilitation or other acute care facility) and poor outcome (defined by death, tracheostomy and gastrostomy, or discharge to institutional care) based on time to surgery both on a continuous scale as well as dichotomously. Greater delay in surgery was associated with greater likelihood of discharge to institutional care with an OR = 1.17 (95% CI: 1.05–1.31; $P = 0.005$) and poor outcome with an OR = 1.12 (95% CI: 1.02–1.23; $P = 0.02$) (25). In the dichotomous analysis there was no difference in outcomes within 24 or 48 hours but increased odds of poor outcome after 72 hours (OR = 1.52, 95% CI: 1.07–2.16; $P = 0.02$). Discussion of the predictors for surgery concluded that craniectomy before herniation might be a more important factor, especially in patients who do not have significant decompensation prior to 48 hours from stroke onset [25]. Of course, this study also must be looked at with a cautious eye as the data collected were based on diagnostic coding as opposed to the more traditionally utilized data including NIHSS score, premorbid mRS, and distribution or size of infarct area. Still, the most interesting finding was that practices for timing of craniectomy did not seem to have any relationship to the year of operation as one might predict if the previously discussed clinical trial data were being utilized as recommendations for changing clinical practice [25].

POSTERIOR CIRCULATION INFARCTIONS AND DECOMPRESSION

While a great deal of research has been directed toward determining the benefits of decompressive surgery in malignant MCA infarctions, there are limited data regarding aggressive treatment of patients with edema from cerebellar infarctions. Possibly more menacing than even large hemispheric strokes, those in the posterior circulation and affecting the cerebellum can lead to life-threatening upward herniation with only small increases in swelling due to the limited space in the posterior fossa. Suboccipital decompression (SDC) has been performed in the setting of brainstem compression and obstructive hydrocephalus as a life-saving therapy. Unfortunately, there have been no randomized controlled studies to suggest the actual benefit of this procedure nor research into which patients would likely benefit the most.

From March of 2007 until September of 2015, records of 1162 patients admitted to one of five hospitals in Korea for cerebellar infarction were reviewed and selected for a case-control study of SDC versus medical management. Twenty-eight patients who had undergone SDC and 56 who had not were reviewed and assessed using multiple logistic regression propensity score matching based on having had a cerebellar infarction volume ratio between 25% and 33% with a Glasgow Coma Scale score greater than or equal to 9 and no clinical deterioration prior to 72 hours from symptom onset. Insertion of an external ventricular device for cerebrospinal fluid drainage as treatment for hydrocephalus was performed in patients with findings of significant hydrocephalus, including 50% of those patients who underwent preventive SDC and 90.6% of those requiring emergent intervention [36]. At follow-up 1 year after the infarction, 66.7% of those receiving SDC had a favorable outcome ($P = 0.030$), defined as mRS of 0–2, versus 51% of those who had not undergone SDC ($P = 0.030$) [36]. The results from this case-control series indicate that *preventive* SDC prior to signs of brainstem compression or obstructive hydrocephalus in patients with an infarct volume ratio of 0.25–0.33 may be beneficial.

Even with the results of this study, there is still a great need for further research into the characteristics of those patients who have suffered a cerebellar infarction and will have overwhelming cerebellar edema leading to increased morbidity and mortality associated with brainstem compression or infarction. While not the main focus of this chapter, it certainly is an important area for future research.

QUALITY OF LIFE

Ultimately, each of these individual studies and meta-analyses demonstrates that while neurosurgical intervention has a clear survival benefit in nearly all patients with malignant MCA syndrome, the evidence of a beneficial difference in morbidity depends on the authors' definition of "good" outcome. Similar to the opinions espoused in the discussions of the more recent meta-analyses, we feel very strongly that a patient's individual beliefs and goals of care need to be weighed when deciding to move forward with surgical decompression in the setting of malignant edema. The data suggest a trend toward an increased representation of patients with outcomes that would allow for a life at home, albeit many will require significant help from family members. Review of those same studies shows a statistically

significant increase in the number of patients who survive with an mRS of 4 that would almost certainly mean a life relegated to living with dependence on others for all of their needs.

Quality of life (QoL) data were collected in most of these trials either prospectively or retrospectively and reveal that relatively few patients or family members regret the decision to undergo surgery despite the ultimate level of dependency [26, 37]. A review of seventeen studies of craniectomy in malignant edema reported outcomes for QoL with data available for six of those trials that looked at scores of overall QoL. Patient QoL measures were in a range of 60% to 67% (an outlier in the DESTINY study of 46% was noted) as compared to best possible QoL [38]. Depression among patients has been reported as mild to moderate in almost 50% of survivors and severe in 15% [38]. While these values may appear to be relatively high, in view of the fact that patients with more severe disability were also included in these analyses, it suggests that patient perception of disability may change or be different at baseline than previously believed [39]. This divide in the acceptability of outcome can be demonstrated when neurologists, neurointensivists, and neurosurgeons were polled: only 38% believed an mRS of 4 to be a favorable outcome [40]. Do patients simply adapt to a disability and life they never before would have accepted?

The answer to that question is exceedingly complex and requires an intimate knowledge of the patient's previous insights and life goals. As would seem obvious, most of the patients who present with a massive ischemic infarct were not expecting or planning for this abrupt change in their lives. Further complicating the situation is that many individuals have neither had a conversation with their legally authorized representatives nor documented their wishes in an advance directive. Even if a person had indicated their general wishes, the circumstances surrounding malignant brain infarction are unique enough that patients and family will need to extrapolate from their prior constructs to the specifics of their current medical condition. Moreover, the physicians caring for them did not have a prior relationship with the patient or their loved ones, though their primary care providers might be able to provide insight into the patient's wishes. It is our practice to look at each individual patient and discuss with the family and patient, if possible, the wide array of outcomes that may occur in the setting of potential malignant brain infarction. This conversation unfortunately relies on a great many unknowns and can be easily directed by the framework in which it is presented.

OPINIONS FROM EXPERIENCE

Reviewing the data from these trials suggests that in patients under age 60 decompressive craniectomy has both mortality and morbidity benefits, though the morbidity must be carefully defined as including the possibility of need for around the clock care. While none of the previously discussed studies analyzed data dichotomized by early versus later surgery, a study from China looked at "ultra-early" surgical decompression in those with an NIHSS score greater than 20 and imaging suggestive of impending herniation syndromes at an inflection point of 6 hours. This study found a statistically significant reduction in mortality in surgically treated patients as well as compromised function as based on Glasgow Coma Outcome scores, with no increase in surgical complications if operated on before or after 6

hours from time of stroke onset [41]. Thus, we believe, pending new research findings, that patients requiring hemicraniectomy should be treated within 48 hours of symptom onset, and not after the patient begins to demonstrate findings of progression from malignant edema. That being said, we appreciate that the glyburide treatment studies published to date, GAMES and GAMES-RP, recommended decompressive craniotomy only after the patient exhibited symptoms and signs of deterioration (defined as Glasgow Coma Scale score ≤ 8 , increase of ≥ 1 on item 1a of the NIHSS score, new pupillary abnormalities, or less brisk response to pain) to have time to determine the efficacy of medical therapy alone prior to surgery [42, 43].

In our own experience, we find hemicraniectomy to be infrequently advised within an early timeframe in the hope that optimal medical therapy will allow some patients with large MCA territory infarcts to “sneak by” without surgery. Often, surgical options are explored only after it is thought that medical optimization has taken the patient as far as it can and by this point there are signs of impending or active herniation (i.e., decrease in consciousness, pupillary changes, or evidence of vascular compromise of the non-infarcted hemisphere). Does holding off on surgery lead to irreversible damage that ultimately leaves the patient with increased disability and a higher likelihood of being classified as an mRS 4 instead of a 3? Might earlier surgery spare brain tissue at risk for infarction or anatomical distortion as suggested by observations in study patients treated with glyburide for prevention of brain swelling as well as laboratory observations in rats [44-46]?

Figure 5: Algorithm for Hemicraniectomy Decision in Malignant Cerebral Infarction as developed by Streib et al. [35] (Reprinted from *Neurology Clinical Practice*, 6(5), Streib et al, Early decompressive craniectomy for malignant cerebral infarction: Meta-analysis and clinical decision algorithm, Pg 440, 2016, with permission from Elsevier).

There is an important role for early patient and family (or legally authorized representative) discussions to be conducted for patients at high risk for malignant infarction. To determine the most appropriate direction of care, a good understanding is necessary of

what a patient may consider to be a reasonable outcome and in turn the care provider should describe the most objective outcome probabilities based on the data available. Streib et al. created a clinical decision algorithm that dichotomizes decisions based on whether a patient would find a life dependent on others acceptable. In their estimations for patients under the age of 60, when an mRS of 3 is considered acceptable QoL, there is a 35% likelihood of poor QoL with only a 43% likelihood of good QoL, whereas when an mRS of 4 is defined as acceptable, then those likelihoods are 9% and 69%, respectively [35]. For patients older than age 60, the likelihood of good outcomes is more restricted, as represented in Figure 5.

FUTURE DIRECTIONS

The meta-analyses discussed here are not the final statement for the care of patients with malignant MCA infarctions. The protocols demonstrate regional and individual physician treatment preferences, especially for medical management. In fact, there are now American Heart Association/American Stroke Association guidelines for medical management for patients at risk for severe brain swelling following stroke, though many of the interventions have not been critically evaluated [47].

Further research on and discussion of the ethics of decompressive surgery should acknowledge that decisions are often made within the context of time constraints and the stress of critical illness and are deserving of further exploration. The collaboration of stroke neurologists, neurointensivists, neurosurgeons, patients, and their families is paramount to the improvement in outcomes for patients with malignant edema from ischemic infarction. Ideally, an institutional protocol for directing conversation between disciplines should be developed and implemented, thus creating a pathway for this decision making process.

CONCLUSION

Large territory, “malignant,” ischemic infarcts are associated with exceedingly high morbidity and mortality. In the past 20 years, multiple studies [24, 26, 27, 29, 32, 33] have been undertaken to establish the benefits of surgical decompressive craniotomy. Results have been mixed demonstrating a paradoxical improvement in mortality and good outcomes, but at the cost of an increase in poor outcomes. Currently, there is no consensus with regard to the timing of surgical intervention and which patients will benefit. Review of the available literature [25, 29, 30, 34, 35, 37] suggests that surgery continues to be an individually applied treatment, though likely with the greatest positive impact on patients under the age of 60 and those who have decompressive surgery within the first 48 hours from symptom onset. Continued collaboration between neurologists, neurosurgeons, neurointensivists, and patients and their families to identify the patients whose clinical presentation and goals of care align with intensive therapy, including early surgery, is vital to providing the best chance for each patient to achieve a desirable outcome. Finally, should new brain anti-swelling drugs become available, the concepts outlined will need to be re-examined within a new management context.

DECOMPRESSIVE CRANIECTOMY IN DIFFUSE INJURY: INTERPRETATION AND IMPLICATIONS OF THE INTERNATIONAL DECRA RANDOMIZED TRIAL

D. J. Cooper*, A. Udy, A. Nichol, J. V. Rosenfeld and M. Hunn
Monash University Australia, Australia

ABSTRACT

The Decompressive Craniectomy in diffuse traumatic brain injury (DECRA) randomized trial unexpectedly found that decompressive craniectomy (DC) surgery effectively controlled ICP but increased the proportion of vegetative survivors, and decreased the proportion of independent functioning survivors. The results led to a reconsideration of the indications for DC surgery after severe TBI, and to an understanding that complications of DC surgery likely outweigh benefits for many diffuse injury patients.

Keywords: DECRA, head injury, outcome, decompressive craniectomy

INTRODUCTION

Intracranial pressure (ICP) monitoring and maintaining control of ICP below agreed limits are fundamental to intensive care therapy for traumatic brain injury (TBI) patients [1]. Increased ICP is associated with worse functional outcomes following TBI, in part because increased ICP is a marker of brain injury severity and in part because increased ICP may further worsen secondary brain injury. Which of these two factors is the most dominant in contributing to worse functional outcomes is unknown. However, although the initiation and

* Corresponding Author's Email: jamie.cooper@monash.edu.

intensity of many therapies depend on it, ICP monitoring and control have not been demonstrated in randomized trials to improve TBI patient outcomes [2].

In patients with refractory intracranial hypertension, decompressive craniectomy was known to control ICP, even though DC surgery did not influence the brain swelling underlying the increased ICP. A randomized trial of DC might therefore test not only the efficacy of DC surgery itself to improve patient outcomes, but might also test the construct that improved ICP control alone should, of itself, decrease the cascade of increased ICP insults, decrease secondary brain injury, and be better for patients' outcomes. In other words, a randomized trial of DC surgery might be one way to objectively test the real benefit of tighter ICP control for reducing secondary brain injuries and improving outcomes.

A small randomized trial in pediatric TBI suggested that DC led to better ICP control and improved outcomes in children [3]. However, larger, randomized trials in adults were required to balance the many potential confounders and establish whether the theoretical benefits of DC for improved long-term functional outcomes were real.

Prior to 2000-2002, when randomized trials of decompressive craniectomy were planned, the use of DC surgery was increasing in both civilian and military TBI patients, and in some settings, even prior to ICP monitoring [4]. Uncontrolled and controlled case-series suggested DC was a highly effective method of ICP control, and better patient outcomes seemed likely. DC surgery was also being increasingly discussed for low and middle-income country applications, where modern intensive care was unavailable but neurosurgery was potentially feasible.

DECOMPRESSIVE CRANIECTOMY (DECRA) TRIAL

The Decompressive Craniectomy in diffuse traumatic brain injury (DECRA) randomized trial [5] enrolled patients with severe TBI when their ICP became refractory to all standard intensive care therapies (sedation, osmotherapy, paralysis, and repeated extraventricular drainage [EVD] of cerebrospinal fluid), but before use of "second tier therapies," i.e., hypothermia and barbiturates. To be designated *refractory*, ICP elevation was sustained longer than 15 minutes in the absence of any patient stimulation. DECRA employed the accepted standard ICP upper limit (>20 mm Hg) to trigger all clinical ICP therapies and also for the trial randomization. DECRA addressed the question which of two alternative "second tier" therapies, DC surgery or optimized medical therapy with barbiturates, would best improve the ICP of patients with severe TBI and their long-term functional neurological outcomes. The ICP randomization trigger of consistently greater than 20 mm Hg was chosen because international guidelines at the time used 20 mm Hg to initiate all therapies for intracranial hypertension, and it seemed likely that requiring longer periods before randomization, by setting a higher ICP threshold to be reached (such as 25 or 30 mm Hg), might increase secondary brain injury during the intervening period, impair outcomes, and decrease the potential to determine a benefit from DC, if one existed. Of note, after the DECRA publication, the fourth edition of the Brain Trauma Foundation Guidelines raised its recommended ICP threshold for usual therapies to 22 mm Hg [1].

The DECRA trial, therefore, assessed a specific surgical procedure (DC) compared to a common medical alternative. It also provided a unique opportunity to learn more about the

fundamental construct underlying many therapies for severe TBI patients, namely, that better ICP control below accepted targets will reduce secondary brain injury and improve outcomes. Nevertheless, this opportunity to learn would require an understanding that all therapies may have undesirable complications, and DC surgery would be no exception.

EXCLUSION OF PATIENTS WITH FOCAL MASS LESIONS

The issues of concern to the DECRA investigators are equally important for all types of patients with severe TBI. However, fundamental differences in the management of patients with diffuse injury versus those with focal mass lesions led the DECRA investigators to exclude mass-lesion patients from this high quality randomized trial. In the presence of mass lesions (hematomas and large contusions), neurosurgical equipoise is less widespread. Surgeons differ on leaving the bone out after an initial mass lesion evacuation and also on indications for a second craniectomy. Furthermore, other recent randomized trials of ICP therapies in TBI patients [6] have suggested that these two distinct patient cohorts (diffuse injury versus mass-lesion) may respond to ICP therapies in opposite directions, and this might confound an ability to detect the real outcome differences. Because of the heterogeneity of the surgical and medical groups, interpreting results would have been difficult if DECRA included both patients with diffuse injury and those with focal mass lesions. Seeking a definitive trial design and clear results that might translate to patient care, DECRA chose to study diffuse injury TBI patients only.

RANDOMIZATION AND TREATMENT OF PATIENTS WITH DIFFUSE INJURY

In DECRA, patients were randomized *after* optimized sedation, positioning, ventilation, osmotherapy, paralysis and intermittent cerebrospinal fluid drainage via an EVD, but *before* the three therapies often described as *second tier* – hypothermia, barbiturates, or DC. These were all untested in randomized trials, and so DECRA compared two of them – DC versus optimized medical therapy usually with barbiturates. Induced hypothermia was avoided. Late “rescue” craniectomy after 72 hours was permitted in the control group of medical-therapy patients for ethical reasons.

DECRA did not include hypothermia therapy as a treatment option. During trial design it was considered that all the three second-tier therapies were equally untested, and that hypothermia for early refractory ICP was being examined in a different randomized trial [7]. Including hypothermia as an option in either the control medical therapy or DC study groups may also have confounded detection of real outcome differences between the DC surgery and barbiturate coma. In time, the *Eurotherm* trial was published and suggested that induced hypothermia in a similar setting controlled ICP but was detrimental to patient outcomes; therefore, the decision reached during design of DECRA was found to be advantageous in retrospect.

Although several different technical variations of bilateral DC surgery exist, DECRA pragmatically tested the procedure that was most accepted by neurosurgeons in the

Australia/New Zealand region, and felt to be associated with the lowest rate of surgical complications. Bilateral craniectomy was chosen because trial patients had bilateral diffuse injury, and the surgical technique was based on the only published series to have reported improved patient outcomes compared to a (retrospective) control group [8]. The DECRA surgery included wide bi-fronto-temporo-parietal craniectomy to minimize injury to the brain on the edge of the craniectomy during swelling beyond the skull margins, avoidance of damage to the sagittal sinus by not dividing the falx cerebri, and bilateral dural openings to maximize pressure reduction. Cranioplasty was conducted months later, in a second surgery procedure.

The DECRA trial randomized 155 adults over 7 years starting in 2002. Eligible patients were younger than 60 years old with diffuse severe TBI, and had intracranial hypertension refractory to first tier therapies. Patients were recruited in Australia, New Zealand, and Saudi Arabia. Patients with bilateral unreactive pupils were excluded, owing to their poor prognosis. To maximize potential benefits and to avoid secondary brain injury from persistent intracranial hypertension, patients were enrolled after all first tier therapies including EVD drainage had been optimized, and for whom, in the absence of patient stimulation, ICP remained above 20 mm Hg for more than 15 minutes. An automated system was used to conceal allocation to treatment group, and patients were balanced between sites and for use of EVD drainage. Physicians and nurses in hospitals were not blinded, but the primary outcome assessors were centralized and blind to treatment allocation. Patients in both groups were well balanced with respect to age, motor score, injury severity score, secondary insults, and computed tomography grading of injury severity. By design, no patient had dilated pupils, but by chance there were more patients with unreactive small pupils in the craniectomy group.

RESULTS

In this trial, DC surgery was clearly more effective to control intracranial hypertension than optimized medical therapy. DC surgery also decreased time on the ventilator and time in the Intensive Care Unit. However, neurological outcomes at 6 months did not favor DC surgery. Compared to optimized medical therapy, DC did not change mortality (18% vs. 19%). DC surgery was associated with an increased proportion of vegetative survivors (12% vs. 2%) and of all non-independent survivors (51% vs. 33%). The proportion of good outcome survivors was halved (4% vs. 9%). The unadjusted overall measure of neurological function used in the trial was significantly worse after DC, as was the same measure after the preplanned adjustment for key variables. After post-hoc adjustment for the only unbalanced baseline measure (pupils), the trend to worse long-term outcomes remained clear, but no longer significant. At the same time, DC surgery had a higher complication rate than medical therapy. Specifically, there was a 10% rate of hydrocephalus requiring a shunt compared to just 1% in medical patients.

The DECRA trial informed clinicians that in patients with severe diffuse TBI, DC surgery after carefully optimized first-tier therapies more effectively controls ICP but does not improve patient outcomes. Further, DC surgery increased the proportion of vegetative and severely disabled survivors, and did not increase the rate of good outcome among survivors.

The DECRA trial results were unexpected, concerning, and controversial. Given the intense focus of clinicians worldwide on meticulous ICP control in severe TBI patients to minimize secondary brain injury, the finding that using surgery to achieve better ICP control not only failed to improve patient outcomes, but led instead to worse outcomes overall and to more severely disabled survivors, was disturbing.

LESSONS FOR CLINICIANS

We believe that the primary lesson from DECRA for clinicians is that before considering DC surgery in diffuse TBI patients with ICP consistently above 20 mm Hg, first tier therapies including EVD drainage and paralysis and then medical therapy including barbiturates should be optimized. It is unknown whether DC surgery would be effective to improve patient outcomes when restricted to use after barbiturates have failed in the ICP therapy cascade. However, no signals from DECRA support this suggestion. DECRA did not address the question of DC surgery after higher ICP thresholds (25 or 30 mm Hg) are exceeded.

The DECRA findings were likely correct because the trial design was rigorous and the patient groups were well matched for all variables other than small pupil reactivity. The chance difference in pupil reactivity has been much discussed, but in the context of excellent baseline matching for age, Glasgow Coma Scale motor score, and computed tomography score, and given that small pupils may be unreactive early in TBI due to drugs and/or external trauma, it seems highly unlikely that this single difference in one baseline characteristic could account for the overall DECRA trial conclusions.

INTERPRETATION AND IMPLICATIONS OF UNEXPECTED FINDINGS

Why then would a randomized trial deliver findings so different from those expected? The most likely explanation is that early after severe TBI, the negative impact of DC surgery and its complications outweighed potential benefits, and exceeded those of barbiturate coma therapy when supported by modern intensive care. Although the surgical complication rate in DECRA was less than previously reported for DC surgery, hydrocephalus requiring a shunt occurred ten times more frequently in the DC treatment patient group. Post-operative hydrocephalus may impair long-term neurological function. DC surgery also brought with it a need for transport to the operating room at a time when patients were maximally unstable after TBI. It also required a second surgery – the delayed cranioplasty, which may have its own complications including infection. The two surgical procedures and the surgical complications were all avoided in the medical therapy control patients.

Another possible explanation of the unexpected findings is that the negative impact of DC surgery is in part related to brain shift and herniation leading to direct injury or ischemia at the edges of the craniectomy due to cortex herniation through the surgical site, or to stretching or shearing of deep white matter axons during herniation. High-resolution multi-modal magnetic resonance imaging in survivors may provide future insights into these possibilities. Disturbances of autoregulation and of cerebral blood flow are also likely after craniectomy and may have contributed. Finally, the unusual but debilitating “syndrome of the

trephined" [9] after craniectomy, and prior to cranioplasty, likely contributed to negative outcomes in some DC surgery patients.

Another important consideration is that in the context of modern intensive care as practiced in the three countries participating in DECRA, optimized medical treatment including barbiturate coma therapy has become a relatively safe treatment option for intracranial hypertension. Barbiturate therapy has been associated with immune suppression, infectious complications, and cardiac depression [10], but these complications were infrequent in DECRA and likely easily managed without adverse effects on patient outcomes. Further, the significantly longer period of intensive care support, which was mandated by the mechanical ventilation support for long-acting barbiturate therapy, may have been beneficial for the early recovery of the swollen TBI brain. The effective and immediate ICP control experienced by DC surgery patients occurred even though the underlying brain swelling was usually continuing at this early time after injury.

A major implication of the DECRA findings derives from the fact that the purpose of DC surgery is control of ICP, but not control of the brain swelling, which underlies rising brain pressure. After DC surgery including removal of both skull bone and dural opening, post-traumatic brain edema must continue its natural course, even though ICP measurements are no longer a valid indicator of the edema severity. Further, DECRA reported shortened ventilator and Intensive Care Unit times after DC surgery, which likely occurred because clinicians acted upon the lower ICP measurements and withdrew sedation and osmotherapy earlier after DC, than they did in the medical therapy patients. After DECRA it seems likely that best long-term outcomes after severe TBI will be achieved by continuing mechanical ventilation support and the brain swelling therapies until brain edema and brain swelling has visibly subsided. Following DC surgery, ICP below conventional pressure thresholds is clearly no longer a useful indicator of brain swelling, and perhaps should now be supplanted by either much lower ICP thresholds [11] or other means (e.g., visual assessment of brain herniation) of assessing ongoing brain edema.

The DECRA trial findings suggest that the ICP threshold for targeting intensive therapy below 20 mm Hg may be too low. Complications from DC surgery may have outweighed benefits in patients with an ICP of 20 mm Hg, but perhaps not at an ICP of 30 mm Hg. A rising ICP may eventually cause death from brain herniation, and DC surgery would likely prevent this outcome. The optimal ICP pressure thresholds for different medical and surgical interventions may not all be the same, and should be carefully reconsidered.

Two interventions, DECRA [5] and rescue hypothermia [7] for early refractory ICP have now been tested in randomized trials and found to improve ICP control but concurrently to increase patients' long-term functional disability. These findings do not mean that other interventions intended to reduce brain swelling from occurring might not be beneficial. For example, prophylactic hypothermia might slow the development of brain swelling with all its implications at an early stage after injury, and thereby both decrease ICP and improve patient outcomes. The ongoing POLAR randomized trial [12] addresses this question.

Finally, it is important to consider the likelihood of bias in a randomized surgical trial where double blinding was impossible. DECRA eliminated bias at randomization by allocation concealment, and at also outcome assessment by blinding, but could not blind clinicians during the intensive hospital period. It is therefore possible that unconscious bias may have led to treatment withdrawal less frequently in the surgical patients. This potential bias cannot be measured, but may in part explain the greatly increased frequency of

vegetative survivors after DC compared to medical management. The trial, however, likely mimics the real world, and such an effect of DC, if true, likely also occurs in usual patient care – to the detriment of patients and families.

Many of the DECRA trial findings were supported by the second large randomized trial of DC surgery for severe TBI. The Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure (RESCUEicp) [13] studied a mixed group of severe TBI patients with both mass lesions and diffuse injury, randomized at a later time point after injury – following hypothermia, and at a higher ICP threshold of 25 mm Hg. In this setting, RESCUEicp found improved patient survival, but at the cost of more vegetative and severe disability survivors. Neither trial had an increase in fully functionally independent survivors, who are usually described as “favorable outcomes.” A subgroup analysis from RESCUEicp separating mass lesion and diffuse TBI patients is awaited and may assist further understanding of both of these randomized trials. Meanwhile, the key findings that dependent poor-outcome survivors were increased, whether DC surgery was conducted earlier [5] or later [13] in the time course of severe TBI, should lead to a complete reconsideration of the indications for DC surgery in all severe TBI patients.

The DECRA trial results were specific for patients with diffuse injury and bilateral swelling. They do not exclude the potential for DC surgery being a reasonable management option for selected TBI patients. DECRA assessed a single procedure (bi-frontal DC) in a specific context (diffuse TBI). It is possible that a lifesaving DC procedure might be a reasonable choice when the mechanisms of injury, clinical course, and radiology together suggest that the patient has sustained a predominantly focal brain injury. In that context, DC surgery might save a life with potential for an independent outcome. In the future, large comparative effectiveness trials [14] may also enable better outcome prediction and improved selection of patients who might benefit from better targeted DC surgery.

CONCLUSION

After DECRA, when DC surgery is being considered and discussed with families, expectations must be realistic and information about the high potential for a vegetative or a dependent, severe disability outcome should be provided. In the context of treatment options, families should be made aware that, instead of DC, for many patients optimized medical therapy may lead to a longer period in intensive care but also to a smaller chance of a vegetative outcome, and a greater chance of independent survival.

ABSTRACT

Although decompressive craniectomy has been used for more than 100 years in neurosurgery, uncertainties still remain regarding the indications, optimal timing, and effects of decompressive craniectomy on the functional outcome of head-injured patients. In this chapter we discuss the role of decompressive craniectomy for refractory intracranial hypertension following severe traumatic brain injury.

Keywords: decompressive craniectomy, traumatic brain injury, refractory intracranial hypertension, RESCUEICP

* This chapter is partly based on the NEJM publication and subsequent correspondence (references [46, 47, 49]).

INTRODUCTION

One of the major determinants of outcome after traumatic brain injury (TBI) is the severity of the primary injury, which is irreversible. Primary injury, however, invariably leads to the activation of cellular and molecular processes, which mediate further (secondary) injury over the ensuing hours and days [1] and are therefore amenable to therapeutic intervention. These molecular cascades can lead to brain swelling within the confines of a fixed intracranial compartment, leading to increased intracranial pressure (ICP). This can, in turn, compromise the cerebral perfusion pressure (CPP), cerebral blood flow (CBF), and brain oxygenation [2, 3]. Ischemia and cell damage can exacerbate the swelling, forming part of a vicious circle that can lead to life-threatening brain herniation. TBI is associated with extracranial injuries in at least 35% of the cases, and these can further increase the risk of secondary injury due to hypotension, hypoxemia, hypercarbia, pyrexia, and/or coagulopathy [4, 5]. A considerable body of evidence links posttraumatic intracranial hypertension at levels above 20 to 25 mm Hg with excess mortality and worse functional outcomes [6-11]. Similar findings have been shown for reduced CPP at levels below 50 to 55 mm Hg [6, 7, 11].

The control of ICP and preservation of CPP has therefore been the mainstay of neuro-intensive care management of TBI for several decades. Tier-based protocols employing neuroprotective measures such as sedation, controlled hyperventilation, therapeutic hypothermia, hyperosmolar therapies, barbiturate coma, and ventricular drainage have been recommended and are widely used in intensive care units to control intracranial hypertension and facilitate cerebral perfusion and oxygenation [12, 13]. Measures such as hyperventilation, therapeutic hypothermia, and barbiturate-induced coma have been found to be effective in reducing ICP; however, subsequent clinical studies have failed to demonstrate clinical benefit, and in certain instances these therapies may have even caused harm [14-18], possibly due to unfavorable effects on cerebral perfusion [19, 20] or adverse extracranial effects [17].

DECOMPRESSIVE CRANIECTOMY

Decompressive craniectomy (DC) is an operative procedure whereby a large segment of skull (bone flap) is removed; the underlying dura is then opened and left unsutured or a wide nonconstricting duraplasty is performed. This procedure can reduce ICP and maintain or improve cerebral compliance [21, 22]. In the context of TBI, DC can be used as the primary or a secondary procedure. Primary DC refers to leaving a bone flap out after evacuating an intracranial hematoma (mass lesion) in the early phase after the head injury either because of evident brain swelling (brain protruding beyond the margins of the inner table of the skull) or because there is a concern of impending brain swelling in the next few hours to days [23-26]. A secondary DC is performed as part of tiered therapeutic protocols, which aim to control intracranial hypertension. The operation can be undertaken as last-tier (life-saving) therapy when all other measures have failed to reduce ICP to levels below 25–35 mm Hg. Alternatively, it can be performed as a second-tier therapy in patients with less pronounced elevation of ICP (e.g., 20 mm Hg); this can be viewed as a neuroprotective measure [25].

From a physiological viewpoint, DC provides additional space for the swollen brain to decompress with beneficial effects on ICP [21]. The procedure was described by Theodor

Kocher in 1901 [26]. Following his description, Harvey Cushing presented a case series of patients with head injury treated with subtemporal decompression [27]. Cushing reported a surgery-associated reduction in mortality from 50% to less than 15% and concluded that the brain edema and swelling that accompany severe cerebral contusions were best managed with a subtemporal DC. Renewed interest in DC emerged in the late 1960s and early 1970s in the context of TBI as well as ischemic stroke [28-30]. However, its utility was questioned in the late 1970s owing to the reports on poor clinical outcomes [31, 32] as well as animal studies that seemed to suggest that decompression may worsen cerebral edema [33]. With the significant improvements in the prehospital and neurointensive care management of TBI in the past 30 years, along with the widespread adoption of ICP monitoring and tier-based therapeutic protocols, the role of DC was re-examined. A resurgence of interest was seen throughout the 1980s and 1990s with a progressive increase in the number of publications describing its use in TBI as well as in other pathologies causing life-threatening intracranial hypertension [34, 35]. Although there were reports of the survival benefit of DC [35, 36], those studies were largely observational/uncontrolled, and the optimal timing and functional outcome of patients remained unclear.

The 2006 Cochrane Database Systematic Review on the use of DC for the treatment of refractory high ICP in TBI [22] identified only one randomized controlled trial [37]. In that study, 27 children (median age, 120.9 months; range, 13.6–176.4 months) with head injuries were randomly assigned to receive medical management alone or medical management plus bi-temporal DC (removal of a disc of temporal bone measuring about 3–4 cm, with extension of the craniectomy to the floor of the middle cranial fossa; dura mater was not opened). The study showed that DC was associated with a risk ratio of 0.54 (95% confidence interval, 0.29–1.01) for unfavorable outcome (death, vegetative status, or severe disability) at 6 months after injury (non-significant trend) [37].

With the continued dearth of good quality data from randomized controlled trials, questions about the utility of DC persisted, and DC did not feature in the 2007 Brain Trauma Foundation Guidelines for the Management of Severe Traumatic Brain Injury (3rd edition) [12]. Several reports have emerged in the past 10 years addressing differences in TBI surgical techniques, timing of DC, and patient populations [37-41]. While DECRA [42] examined the efficacy of early DC in patients with diffuse injury with an ICP threshold of 20 mm Hg for 15 minutes within 72 hours of injury, the role of DC in the treatment of raised and refractory intracranial hypertension was examined solely in observational studies [43, 44].

RESCUEICP TRIAL

The need for a good quality randomized controlled trial to examine the role of DC in the treatment of intracranial hypertension (> 25 mm Hg for 1–12 hours) refractory to medical treatment was widely recognized, and the RESCUEICP trial was launched in 2004 [45, 46]. This international, multicenter, parallel-group, superiority, randomized trial [46], compared last-tier secondary DC with continued medical management for refractory intracranial hypertension after TBI. The trial included patients with TBI aged between 10 and 65 years, with an abnormal computed tomography scan of the brain, an ICP monitor in place, and raised ICP of more than 25 mm Hg for 1 to 12 hours, despite applying stage 1 and 2 measures

of the ICP protocol. All patients were treated in intensive care according to a stratified protocol (see Figure 1 in [46]) aimed at maintaining an ICP of 25 mm Hg or less. If, despite these measures, the ICP remained above 25 mm Hg for 1 to 12 hours, then at stage 3 of the protocol, patients were randomized to DC with medical therapy or to continued medical therapy with an option to use barbiturates to reduce the ICP.

The surgical treatment was either large unilateral frontotemporoparietal craniectomy (hemicraniectomy) or bifrontal craniectomy [46]. The primary outcome measure was the Extended Glasgow Outcome Scale (GOS-E) at 6 months after randomization. Table 1 lists the secondary outcome measures.

Four hundred and eight patients were recruited to this trial: 206 were randomized to the surgical and 202 to the medical group. No significant between-group variability was observed in terms of baseline characteristics and medical or surgical treatment given prior to randomization [46]. Looking at the primary outcome measure (GOS-E at 6 months), the surgical (DC) group had a significantly lower mortality rate than the medical group (26.9% versus 49.9%). Surgery was found to be associated with higher rates of vegetative state, lower severe disability, and upper severe disability than was medical management, but the rates of moderate disability and good recovery were similar between the groups (see Table 3 and Figure 2 in [46]). The trial pre-specified favorable outcome as upper severe disability or better on the GOS-E and with such prespecified sensitivity analysis, 42.8% of surgical patients had a favorable outcome compared to 34.6% of medical patients ($P = 0.12$) [46]. Using the same prespecified sensitivity analysis at 12 months showed that 45.4% of surgical patients had a favorable outcome compared to 32.4% of medical patients ($P = 0.01$) (see Figure 2 in [46]).

Extended Glasgow Outcome Scale (GOSE) at 6 months
Secondary outcome measure
- GOSE at 12 and 24 months - Mortality at 6, 12 and 24 months - Quality of life at 6, 12 and 24 months - GCS at time of discharge from ICU - Assessment of intracranial pressure control - Time to discharge or death in ICU - Economic evaluation

The trial also showed that the control of ICP was better in the surgical than the medical group. It is therefore not surprising that 37.2% of patients in the medical group eventually underwent a craniectomy and only 9.4% of patients in the surgical group required barbiturates as the failure to control ICP was greater in the medical group [46].

In contrast to the RESCUEicp trial, the DECRA trial [42] showed that patients undergoing craniectomy had worse ratings on the 6-month GOS-E than those receiving standard care ($P = 0.03$) with similar rates of death at 6 months (19% versus 18%). As we

discussed in our correspondence that followed publication of the initial paper in the *New England Journal of Medicine* [47]:

The contrasting results of the DECRA and RESCUEicp trials are due to different hypotheses, inclusion criteria, and therapeutic protocols. The DECRA trial, as compared with the RESCUEicp trial, enrolled patients with a lower intracranial-pressure threshold (20 mm Hg vs. 25 mm Hg) for shorter intervals (15 minutes vs. 1 to 12 hours), after lower intensities of therapy (stage 1 interventions vs. stage 1 and 2 interventions), and within a shorter interval after injury (all patients enrolled within 72 hours after injury vs. 44% of patients enrolled >72 hours after injury). Patients with intracranial hematomas were enrolled in the RESCUEicp trial, but they were not enrolled in the DECRA trial. At enrollment, the populations also differed with respect to expected outcome; the requirement for stage 2 interventions increases the relative risk of death by 60%. Hence, at 6 months, the pooled mortality of 37.5% in the RESCUEicp trial versus 18.7% in the DECRA trial is unsurprising. In addition, our primary analysis showed a significant between-group difference in the GOS-E distribution and a substantial reduction in mortality with surgery; this finding differed from that of the DECRA trial, in which mortality was similar in the two groups. The severity of injury in the RESCUEicp trial underpinned dichotomization in the prespecified sensitivity analysis at upper severe disability (independent at home) or better. Given the high expectation of a poor outcome, the use of a “conventional” dichotomy would be as inappropriate as the use of it in populations with mild TBI (in whom disability-free survival is often attainable).

The survival advantage of DC in the RESCUEicp trial was translated to both dependent and independent living, and this is something that clinicians and family members will need to be aware of when making decisions regarding treatment [46]. It is important to appreciate that the perspectives of patients and their families need to be respected when determining the degree of “acceptable” disability and subsequently whether a craniectomy should be considered. We believe that the concept of shared decision making can play a fundamental role to this end [11, 48].

CONCLUSION

Improved control of ICP with surgery may have accounted for mortality that was lower than that observed with medical management. With a large body of evidence showing that it drives mortality, the treatment of intracranial hypertension will remain important [43, 44]. Future research should also focus on cranial reconstruction and the role of primary craniectomy for acute subdural hematomas, which is the topic of the ongoing RESCUE-ASDH trial (rescueasdh.org). To close, we would like to quote an excerpt from our recently published correspondence in the *British Journal of Anaesthesia* [49]:

In the past, we never advocated for an indiscriminate use of craniectomy, and we are not doing so after the publication of the trial results. However, we believe that the RESCUEicp results have shown that craniectomy can be useful, as long as a thoughtful approach is adopted with involvement of the multidisciplinary clinical team and family members in the decision-making process.

“For those who survive,...focusing on a person’s strengths and abilities rather than their disabilities may help relieve some of the isolation often felt by patients and their families on the long road to recovery.”

Honeybul et al., 2016 [2]

ABSTRACT

High intracranial pressure (ICP) is the most frequent cause of death and disability after a severe traumatic brain injury (TBI). High ICP is usually treated with general maneuvers (normothermia, sedation, etc.) and a set of first-tier therapeutic measures (moderate hypocapnia, mannitol, etc.). When these measures fail to control high ICP, second-tier therapies are initiated, such as barbiturates, hyperventilation, moderate hypothermia, or removal of a variable amount of skull bone (decompressive craniectomy, DC).

Objectives. To assess the effects of secondary DC on outcomes and quality of life for patients with severe TBI in whom conventional medical therapeutic measures have failed to control a raised ICP.

Search methods. We searched the Cochrane Central Register of Controlled Trials, Ovid MEDLINE, Embase, and ISI Web of Science. We also searched clinical trials registries and contacted experts.

* Corresponding author: Email: sahuquillo@neurotrauma.net.

Selection criteria and data collection. Randomized or quasi-randomized studies assessing patients over the age of 12 months with severe TBI who underwent DC to control ICP refractory to conventional medical treatments. The search results were examined and potentially relevant trials were retrieved in full, data extraction performed, and studies assessed for risk of bias.

Main results. Three trials were identified. One involved 27 pediatric patients; the DECRA trial was conducted in three countries and recruited 155 adult patients; the RESCUEicp trial was conducted in 24 countries and recruited 408 participants (both adolescents and adults). Each study compared DC combined with standard care (which might include induced coma and/or cooling of the brain) to standard care alone.

Conclusions and recommendations. 1. In the pediatric population (patients ≤ 18 years old), decompressive surgery reduces the risk of death and other unfavorable outcomes (vegetative status and severe disability) in patients with ICP refractory to medical treatment (low quality evidence). 2. In adult patients with severe TBI, DC in those with refractory moderate high ICP (>20 mm Hg threshold) does not reduce mortality or decrease the risk of an unfavorable outcome (moderate quality evidence). In adult patients with severe TBI and high ICP (≥ 25 mm Hg) refractory to conventional medical treatment, DC has a strong effect in reducing mortality at 6 months (ARR: 19.8%) and 12 months (ARR: 21.5%) after injury. The evidence supporting this conclusion is of high quality. The fact that DC improves the chance for survival but with significant disability needs to be conveyed to the patient's family or legal representatives before DC is conducted.

Keywords: decompressive craniectomy, severe traumatic brain injury, cerebral edema, systematic review, Glasgow Outcome Scale, increased intracranial pressure

INTRODUCTION

Traumatic brain injury (TBI), a major health problem worldwide, has its greatest burden in low- and middle-income countries where 85% of the world's population lives [3]. In the past 2 decades, multiple military conflicts have significantly changed the spectrum of TBI. Motor vehicle crashes and falls are the most frequent causes of civilian TBI-related death, while blast-induced TBI is the most frequent in members of the military [4]. Most victims of TBI, both civilian and military, are young male adults, and because of the long-term disabilities sustained by survivors, severe TBI is a challenge to health systems and a burden on families and the community in terms of monetary cost, suffering, and disability [5].

Despite a much better understanding of the pathophysiology and neurochemical cascades triggered by mechanical trauma as well as technical advances in neuromonitoring, the outcomes of patients with severe TBI seem to have reached a plateau. Clinical trial drugs that were promising in preclinical studies yielded disappointing results when tested in multicenter randomized controlled trials (RCTs) [6]. This failure may reveal that experimental models do not have the ability to accurately simulate human TBI, selection of target populations is inaccurate, studies are underpowered and have low probabilities of detecting clinically relevant effects, or knowledge of the optimal therapeutic windows for the drugs is insufficient. Further reasons could be a lack of penetration of the neuroprotective drugs in the brain, insensitivity of the outcome scales currently available to discriminate the potential benefits of a new treatment, or the intrinsic heterogeneity of TBI. An additional hypothesis is

that severe primary brain damage may be present in some of the patients and that such damage cannot be modified by any available treatments [7].

Decompressive Craniectomy

In recent decades, neurosurgeons and intensivists have shown renewed interest in decompressive craniectomy (DC) for the management of high intracranial pressure (ICP) that is refractory to first- or second-level therapeutic measures. These patients have a dismal outcome if ICP is not controlled quickly. Furthermore, highly favorable patient outcomes have been reported after surgical decompression in small-series retrospective cohort studies and prospective non-randomized studies. However, owing to the weak methodological design of these studies, these favorable outcomes do not prove the effectiveness of this dramatic therapy, and many neurosurgeons are still reluctant to use it. Skepticism about the benefits of this procedure is influenced by the notion—shared by many neurosurgeons—that even if DC does reduce ICP, the functional outcome of the survivors is not improved. Additionally, DC has potential adverse effects such as increased brain edema, subdural collections, hydrocephalus, and brain infarctions. A previous version of this review [8] closed with words from the seminal paper by Kjellberg and Prieto, “We have presented our appraisal of the case material (bifrontal decompressive craniectomy), not so much as proof of its superiority over other methods, but rather as provocation for further critical appraisal of its use” [9]. Now that the majority of results of two long-anticipated randomized clinical trials – DECRA and RESCUEicp — are published [10, 11], we hope to shed light on this issue. This systematic review is focused on closed TBI but excludes all military injuries including blast injuries.

Raised Intracranial Pressure in TBI

High ICP is usually defined as ICP >20 mm Hg when measured within the subdural, intraventricular, or intraparenchymal compartments. In the early 1990s, this was considered the most frequent cause of death and disability after severe TBI [12], and high ICP still remains a frequent cause of such. Juul et al., in a *post hoc* analysis of data from the international multicenter trial of the N-methyl-D-aspartate antagonist Selfotel, showed that the most powerful predictor of neurological worsening was the presence of ICP $\geq$ 20 mm Hg [13]. Traditionally, it was considered that approximately 50% of severe TBIs with abnormal computed tomography (CT) scans had high ICP [12, 14]. However, this incidence has changed significantly in studies published in the past 2 decades. In the dexamethasone multicenter study, only 10% of patients had ICPs above 25 mm Hg [15], while in the Traumatic Coma Data Bank (TCDB) published in 1991, 72% of the patients had ICPs above 20 mm Hg [12]. A possible reason for this fairly large difference is that half the patients in the dexamethasone study had diffuse brain injuries type II, but only 24% of patients were classified in this category in the TCDB [12]. This lower incidence of high ICP is consistent with the DECRA (Decompressive Craniectomy in Diffuse Traumatic Brain Injury) study, which included only 155 of the 3,478 patients screened for eligibility (4.5%) [11]. Reasons for the lower incidence of high ICP in DECRA may be better resuscitation strategies, better and faster transport to referral centers, and much more aggressive treatments of the mass lesions.

Management of High ICP

In most centers worldwide, the treatment of high ICP is based on the recommendations of the “Guidelines for the Management of Severe Traumatic Brain Injury” developed by the Brain Trauma Foundation (BTF). These guidelines are endorsed by most scientific societies worldwide, and they have been translated into many languages and define the core principles for managing severe TBI. These guidelines have been periodically updated since the first version was published in 1996 [16]; the latest version was published in 2016 [17]. The sequence of steps for treating high ICP recommended in the BTF guidelines was based on an algorithm that was published in the first and second versions but was withdrawn in the 2007 version [18]. However, because the terminology (first- and second-tier maneuvers) used in the 1996 algorithm is familiar to clinicians and firmly ingrained in the TBI literature, we have used it in this review. In brief, when ICP is above 20 mm Hg, a set of general maneuvers is recommended (head elevation, normothermia, volume resuscitation, sedation, etc.). If these general maneuvers fail, a set of first-tier therapeutic measures is started. These measures include cerebrospinal fluid (CSF) drainage, moderate hypocapnia ($p\text{CO}_2$ 30 to 35 mm Hg), and mannitol administration. When first-tier measures fail to control ICP, only a few therapeutic options (second-tier therapies) are available unless potentially evacuable mass lesions are detected in the CT scan. Suggested second-tier measures are high-dose barbiturates, intense hyperventilation ($p\text{CO}_2 < 30$ mmHg), increasing mean arterial blood pressure, mild or moderate hypothermia, and DC. Of these, only the use of barbiturates has reached a Level II recommendation (based on Class II evidence) to treat high ICP; other medical and surgical therapies have failed to do so [18].

Despite the recommendations of the BTF guidelines on the use of barbiturates, a Cochrane systematic review did not find evidence that the use of barbiturates improves the outcome in severe TBI [19]. Although barbiturates may reduce ICP, this reduction is not associated with lower mortality or improved outcomes in survivors [19]. Barbiturates lower blood pressure in one of four patients, and this hypotensive effect may offset the beneficial effect of lowering ICP [19]. Because of this lack of effective therapeutic measures, alternatives to barbiturates and in particular DC have been reconsidered in the treatment of high ICP.

DECOMPRESSIVE CRANIECTOMY IN THE MANAGEMENT OF TBI

Historically, removal of different parts and quantities of the skull, with or without opening the duramater or augmentative duraplasty, has been performed in TBI. Kocher was the first to propose DC in patients with clinical symptoms of elevated ICP [20]. Later, in 1905, Cushing made a detailed report on a subtemporal and suboccipital decompression procedure to relieve high ICP in patients with inoperable brain tumors [21]. Decompressive surgery for refractory intracranial hypertension is directed toward improving cerebral perfusion, preventing ischemic damage, and avoiding mechanical compression of the brain (brain herniations), and its rationale is based on the Monro-Kellie doctrine [22]. According to this hypothesis, intracranial volume should remain constant and volumetric compensations should be achieved by shifts in CSF, cerebral blood volume, or brain herniations. Removing a

variable amount of bone, with or without leaving the dura mater open or augmented by a duraplasty, is a fast and effective means of increasing intracranial volume, reducing elevated ICP, and increasing the compliance of the intracranial space [23].

Although DC has no proven effect on the primary brain injury, it could reduce damage caused by secondary lesions such as brain herniations and high ICP. As a consequence of the experience gathered in military conflicts, in which neurosurgeons used DC as a strategy of damage control in the battlefield, it has also been used in civilian penetrating (missile) brain injuries. Intracranial gunshot wound injuries are common in some countries and have a dismal prognosis. The assassination attempt against Congresswoman Gabrielle Giffords in the USA in 2011 involved a shot to the head that was managed with early DC, resulting in an unexpected good outcome. This brought the procedure to the attention of international media [24]. This systematic review is an update of a previous review [8] focused exclusively on closed TBI and therefore excludes any study or report published in the field of civilian or military penetrating gunshot wound injuries.

Types of Surgical Decompression

Decompressive craniectomy can be performed in two very different clinical scenarios. The first option, prophylactic decompression or primary-DC (P-DC), is defined as any bone decompression performed in patients undergoing surgery for the evacuation of any intradural lesion [8] with the aim of preventing expected postsurgical increases in ICP. In these procedures the decision is taken by the surgeon and is usually based on the CT scan or intraoperative surgical findings (brain swelling, a “tight” brain, or difficulties in repositioning the bone flap), or both. Some authors have also proposed the use of P-DC as a therapeutic strategy in the management of some types of brain contusions [25], as a damage control procedure in patients with acute subdural hematomas, or for severe brain swelling in countries with low resources and limited availability of intensive care facilities [26]. For the purposes of this review, all these procedures are considered P-DC. The second option, secondary-DC (S-DC), was defined in the first version of this review as a procedure performed on patients with continuous ICP monitoring to control high ICP that is refractory to first- or second-tier medical treatments [8]. This therapeutic option is used in some centers after first- or second-tier therapeutic measures have failed to control ICP over a predefined threshold. In the category of S-DC, we also included patients who underwent a first surgical procedure to evacuate a space-occupying lesion and who had later developed delayed massive unilateral or bilateral brain swelling, when the purpose of DC was to control delayed high ICP [27].

Surgical Technique

Wide variability in surgical procedures for performing DC has been reported. These variations include small to massive amounts of bone removal, unilateral or bilateral bone decompression, scarifying the dura mater to decrease its rigidity, opening the dura mater or leaving it closed, and sectioning the falx, among others. Localization of bone removal can be unilateral, bilateral, bifrontal, or subtemporal, or it can be expanded to what has been called “circumferential decompression” [27-30]. The closing of the dura mater is also highly

variable and the type of grafts used to augment decompression can be autologous, synthetic, or biological [31].

SYSTEMATIC REVIEW METHODOLOGY

Objective

The main objective of this review was to assess the effects of S-DC on mortality, functional outcomes, and, when possible, quality of life in patients with TBI for whom medical treatment has failed to control high ICP. All randomized or quasi-randomized controlled trials in any language were eligible for inclusion. Quasi-randomized controlled trials were defined according to the *Cochrane Handbook for Systematic Reviews of Interventions* as those trials in which quasi-random methods of assignment were used, i.e., alternation, date of birth, medical record number, etc. [32] Trials not fulfilling these basic criteria were reviewed but excluded from the analysis.

Participants

Included in this review were patients over the age of 12 months with a severe traumatic brain injury and in a coma (post-resuscitation Glasgow Coma Scale score below or equal to 8 points) and who underwent S-DC to control raised ICP that was refractory to medical treatment (analgesia, sedation, muscular paralysis, hyperosmolar solutions, hyperventilation, barbiturates, etc.). As in the previous version of this review [8], only those studies that defined the lesion using a CT scan and monitored ICP were included.

Interventions

In this systematic review, S-DC is defined as bone decompression with the dura mater closed, scarified, left open, or opened and augmented by duraplasty. However, the importance of opening the dura mater in any decompressive procedure was clearly stated by Cushing in 1905: “The mere removal of bone alone does not usually answer as a palliative measure, for, owing to the inelasticity of the dura, sufficient decompression will not ensue until this membrane has been freely incised or removed” [21]. Because several experimental and clinical studies have confirmed this point, studies that performed large bone decompression without opening the dura mater have been included in this review, but considered suboptimal. We excluded all studies in which P-DC was conducted.

Comparisons

Patients receiving any standard medical treatment (regardless of level of intensity) were considered the control group. Standard medical treatment is defined as non-surgical therapy used to control ICP, i.e., hyperosmolar solutions, sedation and paralysis, hyperventilation,

barbiturates, and/or moderate hypothermia. CSF drainage for lowering ICP was also considered non-surgical therapy.

Outcomes

The primary outcome for this systematic review was neurological outcome at 6 or 12 months evaluated with the dichotomized Glasgow Outcome Scale (GOS) [33] or the extended GOS (GOS-E) and categorized into “good” or “bad” outcomes. The GOS-E scale splits each of the original severe disability, moderate disability, and good recovery categories into lower and upper categories and extends the five original GOS categories into eight [34, 35]. The GOS-E increases the sensitivity of the original GOS, but it also decreases the interobserver agreement and, therefore, increases the risk of misclassification in untrained evaluators [36]. Patients with a good recovery or moderate disability according to either the GOS or GOS-E were included in the good outcome group while those who were severely disabled, remained in a vegetative state, or died were included in the bad outcome group. We continued to do so despite the presentation of data in one study [10] with a less traditional dichotomization that involved grouping those with “upper severe disability” of the GOS-E into the category of good outcome [10]. In addition to the original good-bad outcome analysis described in the original protocol, and because this is an arbitrary dichotomization that generates controversies, we have conducted a new analysis including death/vegetative versus alive. We believe that death and survival in a vegetative status are considered bad outcomes, without generating controversy [37]. This way, the interpretation of the results is easier for clinicians, and stands apart from the controversy about at which particular point of the GOS-E the threshold should be placed to define a bad/unfavorable or good/favorable outcome. In the opinion of many, the cutoff to define bad and good outcomes is an arbitrary threshold the definition of which should be left to the patients and caregivers and not to the health providers.

Search Methods for Identification of Studies

In order to reduce publication and retrieval bias, we did not restrict our search by language, date, or publication status. The search was conducted by the Cochrane Injuries Group Trials Search Coordinator. The searched databases, search strategies, keyword searching, and hand searching are described extensively in the complete review published in the Cochrane Library [1]. Both reviewers examined titles, abstracts, and keywords of citations from electronic databases for eligibility. The full texts of all relevant records were obtained and assessed to see whether the record met the pre-defined inclusion criteria. When in doubt, we requested advice from the editorial team of the Cochrane Injuries Group.

Risk of Bias Tool

The risk of bias tool recommended by Higgins and Altman was used [32]. This scale is a domain-based evaluation in which critical assessments are made separately for six different

domains (sequence generation, allocation concealment, blinding, incomplete outcome data, selective outcome reporting, and “other”). Naturally, because of the nature of the intervention in this review, clinicians could not be blinded to the type of treatment to which the patient was allocated; however, the domain of blinding was assessed in such a way that information on blinding of the outcome evaluator could be examined separately.

Measures of Treatment Effect and Data Synthesis

We calculated unadjusted treatment effects using the Cochrane Collaboration's Review Manager (RevMan v5.3) software where possible [38]. Risk ratios and 95% confidence intervals (CIs) were calculated for dichotomous outcomes. In this review, we have also added the absolute risk reduction (ARR) and the number needed to treat (NNT) to avoid the outcome of interest. For calculating ARR and NNT we have used the online calculator available at (<http://ebm-tools.knowledgetranslation.net/calculator/prospective>).

RESULTS

For this review the combined search strategy identified 184 published and unpublished studies, but only three fulfilled the eligibility criteria [10, 11, 39]. All three were prospective parallel RCTs. Investigators from one trial randomized patients in blocks of four [39]. In the other two, the unit of analysis was the individual [10, 11]. Sample size at randomization varied from 27 participants in the study conducted by Taylor et al. [39] to 155 in DECRA [11] and to 408 in the RESCUEicp trial [10]. For a comprehensive review of the characteristics of these studies, the reader is referred to the full Cochrane review [1].

Overall, evidence in this review was produced from trials undertaken in intensive care units at hospitals in 25 countries. Recruitment was conducted between 1991 and 2014. The study by Taylor et al. was conducted at a single site in Australia, with a recruitment period covering 1991 to 1998 [39]. The DECRA study was conducted at sites in Australia, New Zealand, and Saudi Arabia, recruiting between 2002 and 2010 [11]. The RESCUEicp was conducted within 73 centers across 24 countries, but the majority of participants (325) were recruited in either the UK (291) or continental Europe (34) [10].

Age, Gender, and Cause of Injury

The study by Taylor et al. focused solely on children aged 1 to 14 years [39]. The DECRA study included participants aged 15 to 59; the median age was 23.7 years in the intervention group and 24.6 years in the control group [11]. The RESCUEicp study had the oldest participants overall, with a mean age in the intervention group of 32.3 years and a mean of 34.8 years in the control group [10]. Males made up the majority of participants within the review (77% in DECRA and 81% in RESCUEicp). Gender of child participants was not reported in the study conducted by Taylor et al. nor was the cause of injury [39]. In DECRA, 85% of participants had suffered motor vehicle accidents, with the rest of injuries largely being related to bicycle or pedestrian accidents. The RESCUEicp reported a diverse

range of causes of head injury, including motor vehicle accidents (35%), falls (32%), assaults (13%), pedestrian accidents (11%), and other/unknown (9%).

Severity at Baseline

All three studies shared the aim of controlling ICP before considering DC, and each refers to detailed protocols for stages or tiers of ICP-reducing treatment. All of them followed the recommendations given by the different versions of the BTF guidelines [16, 17]. As the question of whether DC is being used to treat early and/or moderate increases in ICP or only to treat ICP refractory to all conventional medical treatment, the threshold used in the different studies was a critically important aspect of eligibility criteria [40]. In the Taylor et al. study, investigators first established a threshold of $ICP \leq 20$ mm Hg with an adequate cerebral perfusion pressure [39]. This was defined initially as a cerebral perfusion pressure > 50 mm Hg, but 2 years into the study (1993), parameters for an adequate cerebral perfusion pressure were then adjusted for age: ≥ 35 mm Hg (1–4 years); ≥ 40 mm Hg (5–8 years); ≥ 45 mm Hg (9–12 years); and ≥ 50 mm Hg (>12 years). Later, in 1997, a final definition for adequate cerebral perfusion pressure was then implemented: ≥ 50 mm Hg (1–4 years); ≥ 60 mm Hg (5–8 years); and ≥ 70 mm Hg (>8 years) [39]. In the DECRA study, treatment threshold for ICP was defined as a 20 mm Hg threshold for more than 15 minutes (continuously or intermittently) within a 1-hour period. In the RESCUEicp, the objective was to maintain an ICP of < 25 mm Hg, to be followed by randomization if this was exceeded in any participant for a period of 1 to 12 hours [10].

Interventions and Comparator Groups

In the Taylor et al. study, children receiving DC underwent a bi-temporal craniectomy in addition to standard care as received by the control group. The intervention involved a 3- to 4-cm disc of temporal bone being removed by extending the opening down to the floor of the middle cranial fossa. The dura mater was left intact and, in a few cases, scarified. According to our protocol, this was considered a suboptimal surgical procedure. Randomization reportedly took place at a median of 16 hours after injury, and in the intervention group, DC was performed at a median of 19.2 hours from the time of injury [39]. No child crossed over between treatment arms. In the DECRA, a bi-frontotemporoparietal DC –without sagittal sinus and falx cerebri division— was performed in adult patients in whom first-tier intensive care therapies did not control ICP. In this study, the mean time from injury to randomization was 35.2 hours in the intervention group and 34.8 hours in the control.

The RESCUEicp trial involved a standard protocol to manage participants with the objective of maintaining $ICP < 20$ mm Hg. DC itself included two options: (a) a large unilateral frontotemporoparietal craniectomy for patients with unilateral hemisphere swelling or (b) a large bilateral frontotemporoparietal craniectomy from the frontal sinus anteriorly to the coronal suture posteriorly and the pterion laterally with a wide dural opening with the option of division of the falx anteriorly for patients with bilateral diffuse brain swelling [10]. The median time for the 92% of participants who underwent DC was 2.2 hours. In this study,

the protocol permitted DC surgery to be performed later at the clinician's discretion if the patient subsequently deteriorated.

The comparator group in all three studies was medical management, variously described between studies as maximal medical treatment, medical treatment, standard care, and/or continued medical management. In the Taylor et al. study, this involved barbiturate-induced coma and moderate hypothermia in all cases [39]. In DECRA, second-tier options for refractory ICP included mild hypothermia, barbiturates or both [11]. In the RESCUEicp, the comparator group was defined as a continuation of standard care, i.e., medical treatment per two predefined stages. Stage 1 procedures might include sedation, analgesia, and ventilation; stage 2 might involve more advanced treatment measures including draining CSF, mannitol, inotropes, moderate hyperventilation, hypertonic saline, moderate hypothermia (35–36°C), diuretics, and steroids. Barbiturates were not included as part of either stage, but were reserved as part of continued medical treatment following randomization. Among the 87% of those allocated to continued medical management, the median time until barbiturate infusion was 1.5 hours and the median duration of this therapy was 52 hours [10].

RISK OF BIAS IN INCLUDED STUDIES

The risk of bias assessments for the three included studies are presented narratively below and graphically in Figure 1.

	Random sequence generation (selection bias)	Allocation concealment (selection bias)	Blinding of participants and personnel (performance bias)	Blinding of outcome assessment (detection bias)	Incomplete outcome data (attrition bias)	Selective reporting (reporting bias)	Other bias
DECRA 2011	+	+	-	+	?	+	-
RESCUE ICP 2016	+	+	-	+	+	+	+
Taylor 2001	-	-	-	+	+	?	-

Figure 1. Risk of bias summary. This figure illustrates the authors' judgments about each domain for each included study. The + sign and green color denote low risk of bias; the - sign and red color denote high risk of bias; the question mark and amber/yellow color denote unclear risk of bias.

Sequence Generation

Two studies were assessed as being at low risk of bias for sequence generation. In DECRA, investigators used a stratified procedure and patients were randomized in blocks of two to four according to both the particular center and the technique used to measure ICP; an automated telephone service was used to convey information to centers. In RESCUEicp, a central telephone randomization service was used, and participants were allocated in permuted blocks of random sizes with stratification according to trial site. In the Taylor et al. study, bias was rated as “high” [39]. This is because, after two allocations of four blocks of children each, investigators apparently changed to using the Zelen method of randomization [41], which requires informed consent after generation of sequence.

Allocation Concealment

Both DECRA and RESCUEicp met criteria for low risk of bias. In DECRA, allocation was performed by independent researchers and conveyed by telephone [11]; in RESCUEicp, concealment was assured because the service employed by the trialists did not release the randomization code until a participant had reached the third stage of the treatment protocol, at which point the decision to perform DC or not was carried out [10]. In the Taylor et al. trial, allocation concealment was initially done using sealed opaque envelopes [39], but this trial has nevertheless been rated as being at a high risk of bias because this method only applied to the first two blocks randomized (8 children), after which Zelen randomization was used and allocation could not be concealed.

Blinding of Participants, Personnel, and Outcome Assessors

Lack of concealment of treatment status is an intrinsic limitation of any decompressive study. All three studies were necessarily judged at high risk of bias for blinding of participants and personnel. Outcome assessors were kept blind to treatment status in all three studies, leading to uniform assessments of low risk of bias for this domain.

Incomplete Outcome Data (Attrition Bias)

Both Taylor et al. and DECRA were assessed as being at low risk of bias for this domain. Taylor et al. investigators planned to conduct analyses by intention-to-treat, but were not required to do so as no participant crossed over and no participant who survived the first week was later lost to follow-up [39]. In the RESCUEicp trial, incomplete data were few and 93% [373/398] of the sample were evaluated at 12 months. Missing outcome data were not imputed, but the investigators performed a sensitivity analysis for the primary-outcome measure in the per-protocol population. The risk of bias for the DECRA study was assessed as unclear for this domain. No patients were lost to follow-up; however, “fifteen patients (18%) in the control group underwent delayed decompressive craniectomy as a lifesaving

intervention, according to the protocol” [11]. Of these, four patients in the standard care group, received DC “less than 72 hours after admission, contrary to protocol” [11]. Investigators reported conducting all analyses according to the intention-to-treat principle; however, the change in the primary outcome on the basis of interim analysis, combined with the fact that so many patients in the control group underwent DC, makes the intention-to-treat analysis of unclear utility.

Selective Reporting (Reporting Bias)

The DECRA was assessed to be at low risk of bias for this category [11] despite the change in the primary outcome noted elsewhere in this review. The RESCUEicp was also considered to be at low risk of bias. In the trial conducted by Taylor et al., all expected outcomes were reported, but in the absence of access to a protocol for this trial, we decided to assess it as being at unclear risk of bias [39].

Figure 2. Forest plots summarize the effect of decompressive craniectomy (DC) on mortality. DC (intervention) versus medical treatment (control). M-H: Mantel-Haenszel. In this chapter we discuss only 6-month mortality. However, the 30-day and 12-month mortality are also included in the full version of this review.

Baseline Imbalances

In the Taylor et al. study, both the control and the treatment groups were well balanced in significant covariates such as age, Glasgow Coma Scale score at randomization, pupillary reactivity, and ICP at baseline [39]. In the DECRA study, randomization did not achieve balanced groups in one of the most significant covariates, pupillary reactivity. Bilateral unreactive pupils were present at baseline in 27% of the patients in the DC arm but only in 12% of patients in the control group [11]. In the RESCUEicp study, both groups were quite

similar at randomization apart from history of drug and alcohol use, and therefore no significant bias was introduced because of the differences of the patients at baseline [10].

EFFECTS OF INTERVENTIONS

Mortality at 6 Months after Injury

All included studies [10, 11, 39] reported results for the 6-month outcome, as summarized in Figure 2. In the pediatric study [39], DC reduced the ARR for death by 19.8% (95% CI: -15 to 48.5%, NNT = 5). In adults, the RESCUEicp trial showed that DC achieved a 22.1% ARR (95% CI: 13 to 31%, NNT = 5). In the DECRA study (lower ICP threshold), no significant difference in the ARR was found. Pooled results for the three studies did indicate that the risk of death at 6 months following injury was lower with DC than medical treatment (RR 0.61, 95% CI: 0.48 to 0.78; participants = 571; $I^2 = 38\%$).

Death/Vegetative versus Alive at 6 Months

Two of the included studies [10, 11] reported these results for the 6-month outcome ($n = 544$). We could not get the results of the Taylor et al. study for this combined outcome. In the DECRA study (lower ICP threshold), an increase in the risk of death/vegetative state was found for this combined outcome. In the RESCUEicp, however, a 15.7% ARR in this outcome was observed (95% CI: 6 to 25%), and the NNT to avoid this combined outcome was seven patients. Pooled results for the two studies did indicate that the combined risk of death and vegetative status at 6 months following injury was decreased by DC versus medical treatment (RR 0.82, 95% CI: 0.66 to 1.02; participants = 544).

Figure 3. Forest plots summarize the effect of decompressive craniectomy (DC) on unfavorable outcome (UO) as defined in the original Cochrane protocol. DC (intervention) versus medical treatment (control). The primary outcomes for this systematic review were neurological outcome at 6 or 12 months, evaluated with the traditional dichotomized Glasgow Outcome Scale (GOS) or the extended GOS (GOS-E). This outcome is analyzed by dichotomizing the GOS/GOS-E into the categories of bad/unfavorable outcome (death, vegetative state, or severe disability) and good/favorable outcome (moderate disability or good recovery).

Six-Month Outcome Categorized as Good or Bad

All three studies reported results for the 6-month outcome ($n = 571$) [10, 11, 39]. Forest plots for this outcome summarize these results in Figure 3.

In the pediatric study, DC reduced the ARR for a bad outcome by 39% (95% CI, 39 to 65%) [39]. The NNT to avoid an unfavorable outcome (death, vegetative status, and severe disability) was three children. In adults, the RESCUEicp trial did show that DC did not reduce the ARR of an unfavorable outcome when compared with medical treatment [10]. In the DECRA (lower ICP threshold), the ARR for a bad outcome significantly increased in the DC group when compared to the standard treatment. The ARR was -19% (95% CI: -3 to -33%) [11]. However, this difference was in part justified by the imbalance between baseline characteristics of the control and treatment groups, as remarked by the authors and also discussed elsewhere [11, 42].

Pooled results indicate no significant difference between DC and medical treatment regarding the risk of an unfavorable outcome at 6 months following injury between groups (RR 1.08, 95% CI: 0.93 to 1.20; participants = 579; studies = 3) albeit heterogeneity was very high, $I^2 = 78\%$.

ICP Reduction

Pooled results for the Taylor et al. and DECRA studies, which reported data in a format suitable for meta-analysis, indicate that DC was superior to medical treatment in achieving a 5-mm-Hg reduction within 48 hours [11, 39]. ICP data from the RESCUEicp could not be pooled, as ICP changes were calculated in multiple ways. Results are consistent, however, with the findings of the meta-analysis and show a positive effect for the outcome of ICP control, manifestly in excess of the goal of a 5 mm Hg reduction following intervention.

DISCUSSION

Since the first version of this systematic review was published in 2006, views on DC in patients with acute neurological injuries have changed significantly. The major shift has been in perceptions of the medical community about the role of DC in the management of acute brain injuries. For most surgeons and intensivists, DC was long considered a “primitive” and “obsolete” surgical procedure for managing refractory increases in ICP. However, multiple retrospective and prospective but non-randomized clinical trials have shown that DC is effective in reducing the risk of death in TBI patients with high ICP and in managing swelling-induced brain herniation in patients with large ischemic stroke or acute spontaneous intracerebral hemorrhages [43-46]. Another reason that explains why DC is on the rise is the influence of the use of DC by military neurosurgeons in war-related head injuries [47]. In addition, robust evidence obtained from multicenter RCTs shows that DC significantly reduces mortality and improves functional neurological outcome in patients with large middle cerebral artery ischemic stroke and brain edema at any age [45, 48-50].

Since our first review was published in 2006, not only the incidence of high ICP but also its definition and evaluation have significantly changed in closed TBI because of the experience in the analysis of many multicenter drug studies funded by the pharmaceutical industry. In the analyses of these trials, two points have been raised: first, different methods were used to define high ICP and to evaluate its burden and the effectiveness of different drug and non-drug therapies in controlling it; second, the number of patients with increased ICP was significantly lower than in studies conducted in the 1990s, as already discussed in the Introduction of this review. The different studies conducted so far have used a wide variety of methods to record ICP data (nurse's end-hour ICP, hourly recordings, minute-by-minute digitally recorded data, etc.), introducing wide variability in the methodology to present the data and summarize it. As a consequence, the summary measures and the methods to analyze ICP are still widely heterogeneous. The mean ICP, the time or the percentage of time above a certain ICP threshold (usually above 20 mm Hg), the standardized area under the curve, or the percentage of patients requiring second-tier therapeutic measures are among these. Thus, the true incidence of high ICP in severe TBI is unreliable, and the effectiveness of different treatments to maintain ICP under control is difficult to determine.

Recently, the "dose of ICP" concept has been proposed and used as the best measure to summarize the burden of ICP [51, 52]. The dose of ICP is defined as the area under the curve above the threshold of 20 mm Hg [51] calculated by using high-resolution ICP recording – ranging from a measure every 6 seconds to minute-by-minute. This methodology allows for calculation of the ICP dose and considers all intensity thresholds above 10 mm Hg, not just the traditional 20 mm Hg threshold [51]. By using this approach, Güiza et al. have been able to show that moderate ICP increases of between 15 and 20 mm Hg are, if sustained, related to unfavorable neurological outcomes [51]. It has been shown that the critical ICP threshold for causing brain damage in TBI patients cannot be generalized and that this threshold is patient-dependent. The ICP cutoff, at which the brain suffers secondary damage, depends on the localization of the brain lesion and its characteristics (focal or diffuse lesion), the insult duration or "dose," age, cerebral perfusion pressure, and the autoregulatory status of the patient. It has been suggested that "pressure times time dose" expressed in mm Hg/hour is a much better measure of the burden of ICP than calculations of frequency or duration of episodes of high ICP [52].

Because of this relatively new information and because we believe this variable was difficult to compare among included studies, we changed the way outcomes in ICP have been evaluated and reported in this review upgrade. In addition, most neurosurgeons and intensivists agree that DC, when appropriately performed, significantly reduces ICP in most patients. In a systematic review on the effect of DC on postoperative ICP, Bor-Seng-Shu et al. showed that DC significantly decreases ICP and increases cerebral perfusion pressure in TBI patients with refractory high ICP [53]. However, the main disagreement and lack of evidence concern whether this ICP reduction is translated to reduced mortality and to a better neurological outcome for the survivors.

SUMMARY OF THE MAIN RESULTS

Mortality at 6 Months

All included studies presented data for the traditional 6-month mortality. In the two studies in which the ICP threshold was the most widely accepted (≥ 25 mm Hg), the ARR for death was significantly reduced. In the pediatric study, DC reduced the ARR for death by 19.8% (95% CI: -15 to 48.5%) [39]. In RESCUEicp, in which the majority of participants were adults, the results showed that DC had an ARR for death of 22.1% (NNT = 5) [10]. In the DECRA study (lower ICP threshold), no statistically significant difference in the ARR for death at 6 months was found between the intervention and the control groups [11]. Pooled results for the three studies did indicate that the risk of death at 6 months following injury was lower for DC than medical treatment (RR 0.61, 95% CI: 0.48 to 0.78). In the two studies in which the conventional ICP threshold was used, the ARR for death at 6 months was significantly reduced, although the risk of bias and the low sample size in Taylor's study made these results statistically non-significant. However, in the DECRA study, DC did not change the ARR for mortality at 6 months [11]. Only the RESCUEicp reported the mortality at 12 months [10]. Again, the ARR for death at this time point was significantly modified by DC compared to medical treatment only. ARR for death at 12 months was 21.5% (NNT = 5) (Figure 2).

In summary, all studies but DECRA showed a very significant reduction in mortality at any time point when DC was used to control refractory high ICP. The characteristics of and caveats about the DECRA study regarding the low ICP threshold to indicate DC and the suboptimal surgical technique have been summarized in this review and discussed in detail elsewhere [42]. The DECRA study showed that when the trigger to define refractory ICP is set low (20 mm Hg), DC is not superior to the standard of care in the management of patients with severe TBI [11].

Death/Vegetative versus Alive Outcome at 6 Months

The evidence that DC improves 6-month mortality in patients with ICP ≥ 25 mm Hg is of high quality for adults but low quality for children. However, similar to the results of DC in malignant infarction, there are concerns that DC may prolong poor quality life by increasing the number of survivors with major disability [45, 48]. The Glasgow Outcome Scale (GOS) is a global scale originally described by Jennet and Bond in 1975 for evaluating TBI outcome [33]. The GOS scale rates a patient's status into one of five ordered categories: dead, vegetative state, severe disability, moderate disability, or good recovery. The lack of positive results in all phase III RCTs led some authors to question the sensitivity of the GOS to detect small but clinically relevant treatment effects [34]. Because of this, the extended GOS (GOS-E) introduced by Jennett et al. in 1981 [35] was the scale recommended by the IMPACT group (International Mission for Prognosis and Analysis of Clinical Trials in TBI) as the optimal outcome scale.

Traditionally, TBI trials have been analyzed by dichotomizing the GOS into the categories of bad/unfavorable outcome (death, vegetative state, or severe disability) and

good/favorable outcome (moderate disability or good recovery). This was essentially an arbitrary decision based on the tradition of considering any type of dependence for activities of daily life as a bad outcome. In the RESCUEicp trial, the authors decided to include patients in the “upper severe disability” category, i.e., patients independent at home, in the favorable outcome group [10]. However, the only justification for this new cutoff that the authors gave to support this decision was that “it was agreed a priori by the trial team and the steering committee that the upper severe-disability category would be included in the definition of favorable outcome” [10]. Therefore, this was another arbitrary cutoff that introduced bias into the interpretation of the outcome results. In addition, Wilson et al. remarked that the highest level of interobserver disagreement when using the GOSE-E was found specifically in scoring this “upper severe disability” category [36].

Because of this, and with all the caveats to be discussed later, for this review we decided to use the conventional dichotomy and then added to the analysis another option, which was to group together dead and vegetative state and compare this outcome with the number of patients who were alive. This is another option available to interpret outcome data in TBI trials, one justified by the fact remarked upon by Weir et al. that any patient in a vegetative state could never be regarded as experiencing a favorable outcome, even if the baseline prognosis is strongly adverse [34]. However, the use of the degree of dependency for the daily life activities to define an unfavorable/bad outcome and who should define this — patients versus health-care providers — are still a matter of debate.

Conventional Dichotomized Neurological Outcome at 6 Months

As described previously, in this analysis we used the conventional cutoff for favorable (good recovery and moderate disability) and unfavorable (death, vegetative state, and severe disability) outcomes. All three studies reported results for this outcome at 6 months [10, 11, 39]. In the pediatric study [39], DC significantly reduced the ARR for a bad outcome by 39% (NNT = 3). In adults, the RESCUEicp showed that DC did not reduce the ARR of an unfavorable outcome when compared with medical treatment [10]. In the DECRA study the ARR for a bad outcome significantly increased in the DC group when compared to the standard treatment [11] (Figure 3). However, this difference was in part accounted for by the imbalance between baseline characteristics of the control and treatment groups [11, 42].

Completeness and Applicability of Evidence

We included three studies, all of which sought to address the questions relevant to this review. Regarding ICP control, the results are quite convincing and in line with most previous non-randomized clinical trials showing that ICP was significantly reduced after DC [53]. Regarding mortality in children, although the results are clear regarding the ARR for death, the results were not statistically significant owing to the small number of patients enrolled. Because of this, the evidence should be considered of “low quality” according to the GRADE guidelines [54]. A rough estimate of the number of children needed to enroll in an RCT to show a significant difference as high as 20%, as shown in the Taylor et al. study, would be 188 patients (94 per arm in a 1/1 allocation ratio) for a power of 80% and an alpha error of

0.05. The results of Taylor et al. in children and of the RESCUEicp for adults make it unlikely that any internal review board would grant ethical approval to enroll patients in a new trial. This is one of the cases in which, although an additional trial could upgrade the degree of evidence, the clinical equipoise for raising the evidence bar could be difficult to achieve or might even be ethically questionable.

All three studies included managed severe TBI patients with high ICP according to some iteration of the BTF guidelines; therefore, the treatments used are consistent with the management that many patients receive in some high-income countries. However, the external validity of the recommendations established here are limited for low- and middle-income countries. This is because the main cornerstone of managing high ICP in all versions of the BTF guidelines is the monitoring of ICP, which is generally available only in high-income countries. Indeed, a major limitation of the current version of this review is that the question of how and when to decide to conduct DC in patients without ICP monitoring cannot be answered. Therefore, clinicians reading this review should not draw any conclusions regarding whether the recommendations given here can be extrapolated to patients managed without any ICP probe implanted. Indeed, the data presented here cannot be integrated to any patient management protocol when any surrogate measures of high ICP, such as the status of the basal cisterns or midline shift in the CT scan, are used. Therefore, the results and recommendations of this review are not applicable outside those institutions in high-income countries where ICP is routinely monitored.

Our review did not allow for in-depth consideration of the complications of DC and the required mandatory second surgery to repair the iatrogenic skull defect in survivors (cranioplasty or bone flap reposition). Early complications of DC have been recorded in most trials, but no trial has documented the complications related to bone replacement or cranioplasty in survivors. Cranioplasty is usually deferred a variable time after DC in different institutions. In addition, the primary endpoint of all three included studies was the 6-month outcome. Some of the early or late surgically related complications of DC are, among others, expansion of preexistent hemorrhagic contusions, development of new ipsilateral or contralateral hematomas (subdural or intracerebral), seizures, CSF leaks, subdural hygroma or brain herniations through the craniectomy defect, posttraumatic hydrocephalus, or the syndrome of the trephined [55, 56]. Kurland et al. conducted a systematic review on the short- and medium-term intracranial complications of DC. In their review they included not only RCTs but all types of studies [56]. This review identified many DC-related complications of three major types: hemorrhagic, infectious/inflammatory, and disturbances of the CSF compartment. Kurland et al. reported that the frequency of complications after DC was 13.4%. On average, 6.4% of the patients presented complications related to bone replacement or cranioplasty [56].

CONCLUSION

- In the pediatric population (patients ≤ 18 years old), decompressive surgery reduces the risk of death and other unfavorable outcomes (vegetative status and severe disability) in patients with ICP refractory to medical treatment. However, the quality of evidence to support this is low and is based on a single-center randomized trial

that showed that DC, even without opening the dura mater, is effective in reducing ICP and mortality, and in improving functional outcome. However, leaving the dura mater intact should be considered a suboptimal procedure, even in a pediatric population. In addition, this study was very small and was assessed to have a high risk of bias on important domains, and so the results must be interpreted with caution. Although ideally these results should be replicated in a larger clinical trial, it is unlikely that any ethical review board would approve a second trial in children on the basis of scientific reasons alone. Because of this, DC is a reasonable treatment to include as a last step in children with high ICP refractory to all conventional medical options. We need to wait for the publication of the RESCUEicp results in children ($n = 56$) to see whether adding new data may improve the quality of evidence for DC in the pediatric population.

- In adult patients (> 18 years old) with severe TBI, DC in those with refractory moderate high ICP (> 20 mm Hg threshold) does not reduce mortality or decrease the risk of an unfavorable outcome (evidence of moderate quality). This conclusion is based on the results of the DECRA study and therefore should be interpreted with caution because of the high risk of bias of the study, the imbalance in the baseline characteristics of the patients, and the suboptimal surgical procedure that was used in this trial. Whether further studies with the same inclusion criteria but different surgical technique will change this conclusion cannot be predicted. In addition, the lack of clinical equipoise to conduct new trials at this lower ICP threshold makes it very difficult to change our certainty in the quality of evidence.
- In adult patients with severe TBI and high ICP (≥ 25 mm Hg) refractory to conventional medical treatment based on the BTF guidelines, DC has a strong effect in reducing mortality at 6 months (ARR: 19.8%) and 12-months (ARR: 21.5%) after injury. The evidence supporting this conclusion is of high-quality and is based on the results of the RESCUEicp trial.
- In adult patients with severe TBI and high ICP (≥ 25 mm Hg) refractory to conventional medical treatment, DC significantly reduces mortality at 6 and 12 months after injury but does not decrease the risk of an unfavorable outcome measured in the traditional way of dichotomizing either the GOS or GOS-E into favorable or unfavorable outcome (death, vegetative state, and severe disability). This conclusion is of high quality and is based on the results of the RESCUEicp. Therefore, increased survival may occur at the expense of surviving with a more or less severe degree of disability. Nevertheless, the degree of disability that should be considered a bad outcome is a matter of considerable debate, and is a variable that should be self-reported by patients and caregivers and not by health professionals who are usually highly biased. In most Western cultures, individuals, if they are able to consent, or their legal representatives, if they are not, are the target of the informed consent. However, in other cultures such as Asian cultures [57], even if the patients are competent, the families have the obligation to protect the common interests of the whole family and therefore they take a very active role in the medical decision process. Therefore, the fact that DC improves the chance for survival but with significant disability needs to be conveyed to the patient's family or legal representatives before DC is conducted. This way, they will have all the information

needed to participate in the medical decision process and take a decision that respects the patient's preferences, expectations, and values.

- An unavoidable major limitation of this review is that how and when to decide to conduct DC in patients without ICP monitoring cannot be answered. Therefore, clinicians reading this review should not draw any conclusions regarding whether the recommendations given here can be extrapolated to patients managed without ICP monitoring. The relatively high cost of ICP monitoring and the lack of robust evidence of its usefulness will probably limit its implementation in low- and middle-income countries in the short-term future. In high-income countries, ICP monitoring is now routinely conducted in many centers managing severe TBI. Therefore, the results and recommendations of this review are not applicable outside those centers where ICP is routinely monitored.

To refine the role of secondary DC in the management of high ICP in patients for whom conventional measures have failed and to increase the level and quality of the available evidence, new clinical studies are still needed, especially in the pediatric population. However, the difficulties in designing, implementing, and funding adequately powered RCTs are considerable. Considering the size of the strong effect that DC has in reducing mortality in adults shown by the RESCUEicp, new trials in adults should focus on identifying the best biomarkers to define survival with an acceptable quality of life, the best timing for DC, the most appropriate surgical technique, and whether some synergistic treatments—hypothermia, barbiturates, or any other neuroprotective drugs—used together with DC may improve the functional outcome and the quality of life of survivors. The better understanding of the pathophysiology of TBI gathered in the past decade, the data obtained from multimodal neuromonitoring, and some of the lessons learned in previous clinical trials should be taken into consideration and applied to any new controlled study.

ACKNOWLEDGMENTS

We gratefully acknowledge the assistance of the following people during the writing of the final report over many versions: Katharine Ker, Review Group Co-ordinator of The Cochrane Injuries Group, for continuous help throughout the writing of the review; Karen Blackhall and Deirdre Beecher, Trials Search Coordinators, for helping us to conduct the electronic searches for this study and in obtaining papers that were difficult to locate; and Paola Tejada, Fundacion MEDITECH, Centro Adherente Cochrane, Universidad Surcolombiana Neiva (Colombia), for providing an independent evaluation of the DECRA study.

Chapter 233

DECOMPRESSIVE CRANIECTOMY IN PEDIATRIC TBI

David S. Hersh, MD and Mari L. A. Groves*, MD

Department of Neurosurgery, University of Maryland, Baltimore, MD, US
Division of Pediatric Neurosurgery, Department of Neurosurgery,
Johns Hopkins University, Baltimore, MD, US

ABSTRACT

Traumatic brain injury (TBI) is the leading cause of death and disability in children older than age 1, adolescents, and young adults. Pediatric patients have unique anatomical and physiological features that influence their susceptibility to both primary and secondary injury. Although the management of pediatric TBI patients previously had been extrapolated from the adult literature, the importance of research studies and practice protocols that are specific to the pediatric population is becoming increasingly recognized. In particular, the indications, outcomes, and complications of decompressive craniectomy in pediatric TBI patients have been reported by various groups. As a result, decompressive craniectomy has been incorporated into the Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents, which recommend that surgery may be considered for pediatric TBI patients who are showing early signs of neurologic deterioration or herniation or are developing intracranial hypertension refractory to medical management during the early stages of their treatment. However, further work is necessary to identify patients who are suitable candidates for decompression, in the ongoing effort to optimize the outcomes of pediatric patients following TBI.

Keywords: pediatric, traumatic brain injury, decompressive craniectomy, cranioplasty

INTRODUCTION

Unique Considerations

Although the literature tends to focus on the use of decompressive craniectomy in the adult population, the procedure is frequently performed in pediatric patients as well. Pediatric patients may undergo a decompressive craniectomy to treat malignant cerebral edema in the setting of a large stroke [1], or rarely severe encephalitis [2, 3]. Most commonly, though, decompressive craniectomy is discussed in the context of patients with severe traumatic brain injury (TBI). This is particularly relevant to the pediatric population, as each year approximately 475,000 children experience TBI, resulting in close to 40,000 hospitalizations annually [4]. Trauma can be particularly injurious to the developing brain, resulting in lifelong neurological, cognitive, emotional, and behavioral deficits [5]. TBI is therefore widely recognized as the leading cause of death and disability in children older than 1 year of age, adolescents, and young adults [6-8].

A number of unique features distinguish pediatric TBI patients from their adult counterparts. In particular, anatomical differences in the size, shape, and consistency of the skull have important biomechanical implications. On the one hand, children have smaller brains than adults and are therefore less susceptible to whiplash injuries caused by angular acceleration [9]. On the other hand, children's heads are large and heavy relative to the rest of their body, while their neck muscles are relatively weak. Additionally, until the skull is fully calcified, it remains relatively soft and pliable, but less able to withstand a bending load or distribute pressure. Biomechanical studies demonstrated that the adult skull can withstand an impact that has eleven times the force relative to a neonate [10]. The compressibility of the soft pediatric skull results in a higher percentage of diffuse axonal "shear" injuries that ultimately produce diffuse swelling and intracranial hypertension, in contrast to adults who are more commonly affected by focal mass lesions [11-13].

While these anatomical features affect the primary injury that follows a trauma, pediatric patients also demonstrate unique physiological features that influence the subsequent secondary injury. In particular, children have an immature cerebral vasculature compared to their adult counterparts, and a long-standing hypothesis has been that cerebral autoregulation is impaired in pediatric patients following a severe injury, resulting in vasodilation and diffuse cerebral hyperemia. The subsequent increase in cerebral blood flow (CBF) and cerebral blood volume (CBV) ultimately produces diffuse cerebral edema and elevated intracranial pressure (ICP) [12-16]. Interestingly, some studies have disputed the concept of hyperemia following TBI, instead reporting that cerebral hyperemia is uncommon in pediatric TBI patients and that CBF values are typically within normal limits [17-21]. Ongoing research is therefore needed to clarify the pathophysiological processes that take place in pediatric TBI patients.

Given the possibility that CBF, CBV, and cerebral metabolism are intrinsically different in pediatric patients and adults, some have questioned whether the definition of intracranial hypertension that is used in adults (i.e., greater than 20 mm Hg) can be applied to the

pediatric population as well. There is some evidence that “normal” ICP ranges are age-dependent, with infants tending to have ICPs in the 2–4 mm Hg range, while older children and adolescents tend to have ICPs in the 5–15 mm Hg range [22, 23]. Infants and young children also tend to have lower cerebral perfusion pressures (CPPs) than adults; one group established a “minimum CPP” of 30 mm Hg in neonates, 40 mm Hg in infants aged 1 month to 1 year, 50 mm Hg in 1- to 4-year-olds, 60 mm Hg in 5- to 8-year-olds, and 70 mm Hg in children older than 8 years [24]. A more recent study examined slightly different age groups, establishing a minimum CPP of 48 mm Hg in 2- to 6-year-olds, 54 mm Hg in 7- to 10-year-olds, and 64 mm Hg in 11- to 15-year-olds [25].

These values become relevant in the setting of TBI, where decreases in CPP can result in cerebral ischemia, a critical mechanism of secondary injury. Given the definition of the CPP as the difference between the mean arterial pressure and the ICP, intracranial hypertension translates into reduced cerebral perfusion, thereby limiting the delivery of oxygen to the injured brain. As a result, it is now common (though not universal) practice to monitor the ICP in severe TBI patients and initiate therapies that lower the ICP once it has surpassed a certain threshold [26–28]. Numerous studies support this practice, having established that sustained intracranial hypertension is associated with poor outcome in pediatric TBI patients [29–33]. However, high-quality evidence for specific ICP thresholds at which to initiate treatment remains limited. The second edition of the Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents, which was published in 2012, provided a Level III recommendation to initiate treatment of sustained intracranial hypertension at a threshold of 20 mm Hg, the same cutoff as in adult patients [34]. The authors of the guidelines pointed out, however, that a lower ICP threshold, as low as 15 mm Hg, may be more appropriate in infants and young children, and that further studies are necessary in order to determine age-specific thresholds.

Indications and Technical Considerations

Regardless of which ICP threshold is used, a number of options are available to lower the ICP once the decision has been made to initiate treatment. Many pediatric trauma centers have specific protocols in place for treating intracranial hypertension and tend to parallel those used for adult TBI patients. First-tier therapies include head of bed elevation, mild hyperventilation, hyperosmolar therapy, cerebral spinal fluid (CSF) diversion, sedation, and paralytics (see Figure 1). Second-tier options for pediatric patients with refractory intracranial hypertension include hypothermia, barbiturate-induced coma, and decompressive craniectomy (see Figure 2) [8, 35, 36]. In this setting, decompressive craniectomy is typically performed in a delayed manner, after ICP-directed therapies have been attempted and failed. This is classified as a secondary decompressive craniectomy. Alternatively, decompression may be performed early in the patient’s hospitalization, when it is most commonly combined with removal of a mass lesion such as a subdural hematoma or a contusion. In this setting, the procedure is classified as a primary decompressive craniectomy (see Figure 3).

Figure 1. A flowchart demonstrating first-tier therapies for the management of intracranial hypertension in pediatric patients (adapted from the institutional protocol of a local Level 1 pediatric trauma center) (Courtesy of M Groves, University of Maryland).

Figure 2. A flowchart demonstrating second-tier therapies for the management of intracranial hypertension in pediatric patients (adapted from the institutional protocol of a local Level 1 pediatric trauma center) (Courtesy of M Groves, University of Maryland).

Figure 3. A 14-year-old boy was struck in the head by a falling tree branch and underwent primary decompressive craniectomy. The initial head CT (A, B) demonstrated a right temporal contusion as well as a 2-cm left extra-axial hematoma with 4 mm of midline shift. The patient was taken for urgent decompressive hemicraniectomy and expansile duraplasty with evacuation of the extra-axial hematoma (C). Postoperative MRI (D) was completed 4 days following decompression, and a subsequent MRI (E) demonstrated ex-vacuo changes with mild enlargement of the ventricles. A cranioplasty was performed (F) and the patient made a full clinical recovery. He has returned to school and is neurologically at his baseline (Courtesy of M Groves, University of Maryland).

A variety of surgical procedures may be performed to lower the ICP, and while they are all classified as “decompressive craniectomies,” each one involves a varying degree of bony removal and/or dural opening. A large, unilateral frontoparietotemporal craniectomy is performed in patients with focal pathology and unilateral swelling and is particularly useful in patients with mass lesions [37]. In patients with diffuse pathology and bilateral swelling, some practitioners continue to perform a unilateral fronto-parietotemporal craniectomy, but other options include bilateral frontoparietotemporal craniectomies or a large bifrontal craniectomy with or without ligation of the anterior sagittal sinus and splitting of the falx [38–41]. The options for dural opening include leaving the dura intact, scoring the dura, or opening it with or without an expansile duraplasty. Wide dural opening has the advantage of reducing the ICP even further than bony decompression alone [42]. At our institution, wide dural opening is always accompanied by an expansile duraplasty using alloderm to graft the dura. A less aggressive option involves unilateral or bilateral removal of the temporal bone in order to prevent uncal herniation [43].

OUTCOMES FOLLOWING DECOMPRESSIVE CRANIECTOMY IN PEDIATRICS: 20 YEARS OF EXPERIENCE

Early reports of decompressive craniectomy in pediatric TBI patients demonstrated mixed results [38, 39]. More optimistic reports began to emerge in the 1990s. A case-controlled study performed by Cho et al. [44] examined twenty-three patients younger than 2

years of age with non-accidental trauma and ICPs greater than 30 mm Hg. Five patients underwent unilateral frontoparietotemporal craniectomy and duraplasty, while five patients underwent bifrontal craniectomy and duraplasty; they were compared to a matched group of thirteen children who were treated medically. The authors found that decompressive craniectomy resulted in a significant reduction in ICP and improved Children's Outcome Scale scores at a mean follow-up of 3.2 years. Similarly, Dam Hieu et al. [45] reported two 8-year-old patients who underwent decompressive craniectomy within 12 hours of presentation after the patients developed intracranial hypertension and clinically decompensated, developing first a unilateral fixed/dilated pupil and then bilateral dilated pupils, despite medical management. The authors documented successive decreases in ICP with craniectomy, dural opening, and debridement of contused tissue. Although the decompression had been performed as a "salvage" procedure, both patients were ambulating and one had returned to normal speech and behavior while the other had returned to school after 6–10 months of follow-up.

A subsequent retrospective case-control study by Polin et al. [40] compared thirty-five severe TBI patients (eighteen pediatric patients and seventeen adults) who underwent bifrontal craniectomies to a cohort of ninety-two matched patients from the Traumatic Coma Databank who were managed medically. The study group was limited to patients who underwent bifrontal craniectomies for diffuse cerebral edema. Patients who underwent decompressive craniectomy in association with the evacuation of a mass lesion were excluded. Bifrontal craniectomy successfully reduced the average ICP from 34.9 to 21.6 mm Hg, while medical management only reduced the average ICP from 33.2 to 29.4 mm Hg. Decompressive craniectomy also had a significant influence on clinical outcomes, with medical management alone having a nearly four-times greater risk of an unfavorable outcome. Subgroup analyses revealed that 44% of the pediatric patients had a favorable outcome, defined as a Glasgow Outcome Scale (GOS) score of 4 or 5, after decompressive craniectomy, compared to only 29% of the adult patients. Additionally, patients who underwent decompressive craniectomy within 48 hours and did not exhibit sustained ICPs greater than 40 mm Hg were more likely to have favorable outcomes. Pediatric patients who met these criteria and underwent decompressive craniectomy had favorable outcomes in 80% of cases, compared to only 24% of the pediatric patients who were managed medically ($P = 0.002$). Nevertheless, the conclusions of the study were tempered by the methodological challenges of using an appropriately matched historical control group, and the need for a prospective, randomized trial became clear.

To date, the only prospective, randomized clinical trial to focus exclusively on decompressive craniectomy in pediatric TBI patients was completed at the Royal Children's Hospital in Melbourne, Australia, and was reported in 2001 [46]. The investigators included all pediatric TBI patients older than 12 months of age who had an intraventricular catheter and demonstrated either intracranial hypertension or clinical signs of herniation during the first hospital day. Intracranial hypertension was defined as an ICP of 20–24 mm Hg for at least 30 minutes, 25–29 mm Hg for at least 10 minutes, or greater than or equal to 30 mm Hg for at least 1 minute, while clinical herniation was defined as unilateral pupillary dilation or bradycardia. During the 7 years of the trial, fourteen patients were randomized to medical management alone and thirteen patients were randomized to a bitemporal 3- to 4-cm craniectomy with occasional scarification of the dura (in addition to medical management). Decompressive craniectomy was effective in decreasing the ICP in 92% of cases, resulting in

a mean ICP of 17.4 mm Hg. In contrast, medical management alone was effective only 71% of the time, resulting in a mean ICP of 21.9 mm Hg. At 6 months, 54% of the patients who had undergone decompressive craniectomy achieved favorable outcomes (defined as a modified GOS reflecting children who were normal, functionally normal, or mildly disabled but independent, as well as a “good” Health State Utility index of 1.00–0.7), compared to only 14% of the patients who were managed medically. These results prompted the authors of the study to recommend early surgical decompression in cases of intracranial hypertension and/or herniation, rather than reserving surgery as a last resort after medical management has failed. However, their results should be interpreted cautiously, given the small sample size, long duration, and short follow-up period of only 6 months. Above all, the bitemporal craniectomies performed by the authors are inherently different from the frontoparietotemporal craniectomies and bifrontal craniectomies that are more commonly performed in pediatric patients undergoing a decompression, making it difficult to generalize their findings.

A number of subsequent case series continued to explore the role of early surgical decompression, but focused on the early use of larger, unilateral decompressive craniectomies. One series of seven pediatric patients who presented with decerebrate posturing and diffuse cerebral edema found that a unilateral frontotemporal craniectomy (the parietal and occipital regions were left intact) and duraplasty performed within 6 hours of the trauma decreased the ICP from over 45 mm Hg to less than 20 mm Hg in all cases and resulted in complete recovery within 5 weeks [47]. Another series of five children with severe TBI and diffuse cerebral edema described the use of a unilateral frontoparietotemporal decompressive craniectomy and duraplasty for clinical and radiographic deterioration within 48 hours of the trauma [48]. (Two patients underwent a true craniectomy, whereas the remaining three patients underwent a “floating” craniotomy.) At follow-up (ranging from 14 to 42 months), all five patients had a favorable outcome, defined as a GOS score of 4 or 5.

Other studies have instead included patients with bilateral decompressive craniectomies. A prospective, observational pilot study by Ruf et al. [49] followed six children with “refractory” intracranial hypertension, defined as an ICP greater than 20 mm Hg for more than 30 minutes despite first-tier therapies and a single dose of barbiturates and mannitol. Three patients underwent bilateral frontoparietotemporal craniectomies, two patients underwent unilateral craniectomies, and one patient underwent a suboccipital craniectomy. The ICPs normalized in five of the six patients, and the authors reported that three of the six patients (including two of the three patients who underwent bilateral craniectomies) were neurologically “normal” after 6 months. The authors therefore promoted the early use of decompressive craniectomy soon after refractory intracranial hypertension has been diagnosed. Similarly, Rutigliano et al. [50] reported thirty adolescents with severe TBI and ICPs greater than 30 mm Hg for an unspecified duration. Six patients did not respond to medical therapy and underwent bifrontal and biparietal craniectomies with a bifrontal duraplasty, ranging from 2 to 26 hours after intracranial hypertension first developed. Of the six patients, five had normal ICPs following the decompression, and five were independent or required minimal assistance upon discharge from rehab. The authors concluded that once intracranial hypertension develops, decompressive craniectomy should be performed as early as possible.

Outcomes following primary versus secondary decompressive craniectomy were further investigated by Kan et al. [36], who retrospectively reviewed fifty-one children with a mean

age of 6.6 years who presented with severe TBI and underwent a large unilateral decompressive craniectomy. A primary decompression was performed in forty-five patients, in whom the craniectomy was performed in conjunction with removal of a mass lesion, while six patients underwent a secondary decompressive craniectomy due to ICPs that remained greater than 25 mm Hg despite medical therapy. Postoperatively, there was a substantial difference in outcome between the two groups. Patients who underwent a secondary decompressive craniectomy had a high mortality rate, with five of these six patients (83%) dying, in contrast to eleven of the forty-five patients (24%) who underwent a primary decompression with evacuation of a mass lesion. However, the survivors in the primary decompression group had a high rate of posttraumatic shunt-dependent hydrocephalus (40% of patients) and posttraumatic epilepsy (20% of patients). Nevertheless, at a mean follow-up of 18.6 months, thirty of the survivors had a favorable outcome as determined by a King's Outcome Scale for Closed Head Injury (KOSCHI) score of 4 or 5 [51]. The authors therefore concluded that they would not recommend a decompressive craniectomy in pediatric patients without a mass lesion. However, the six patients who were included in this category were severely injured, with a pre-operative Glasgow Coma Scale (GCS) score of 3–5, pre-operative ICPs >40 mm Hg, and fixed pupils.

In contrast, other surgical series have produced more promising results. In a retrospective review of twelve pediatric patients with severe TBI and refractory intracranial hypertension (defined as ICPs greater than 20 mm Hg for more than 20 minutes), six patients underwent a unilateral or bilateral frontoparietotemporal craniectomy without duraplasty, while six patients were treated with hypothermia and/or barbiturates [35]. The patients in the surgical cohort underwent decompressive craniectomy an average of 7 hours (range 2–18 hours) after the ICPs had become elevated. All six patients experienced normal ICPs postoperatively, and all had good outcomes at 1-year follow-up. In contrast, despite having less severe imaging findings, the six patients in the non-operative cohort had worse outcomes: two patients died, one patient had a GOS score of 3, and only three patients had a favorable outcome at 1 year. In another retrospective review of eighteen patients with a mean age of 7.8 years who underwent decompressive craniectomy for severe TBI, the median ICP improved from 40 mm Hg to 16 mm Hg and brain tissue oxygenation (PbtO₂) improved from 17.4 to 43.4 mm Hg pre- and post-decompression, respectively [52]. Favorable outcomes were achieved by 78% of the patients, despite having a high rate of pupillary abnormalities and a low GCS score pre-operatively.

Jagannathan et al. [53] were among the first to explore long-term outcomes following decompressive craniectomy in pediatric TBI patients. The authors reported a group of twenty-three children with a mean age of 11.9 years who presented with severe TBI over a 10-year period and underwent decompressive craniectomy for refractory intracranial hypertension (defined as ICPs > 20 mm Hg). Eight patients with mass lesions underwent a unilateral frontoparietotemporal craniectomy with duraplasty, while fifteen patients with diffuse swelling underwent a bifrontal craniectomy with duraplasty and sectioning of the falx. Overall, 65% of the patients in the series had favorable outcomes 2 years later, with 82% of the survivors demonstrating good functional outcomes, suggesting that decompressive craniectomy improves not only the survival of pediatric TBI patients, but also functional outcomes. The authors identified several predictors of outcome, finding that patients with a concomitant vascular injury and/or ICPs greater than 20 mm Hg following surgical decompression had a higher risk of mortality. Additionally, patients who underwent surgery

due to pupillary changes suggestive of impending herniation, rather than refractory intracranial hypertension, had worse outcomes. The patients spanned a wide spectrum, with an average time to surgery of 68 hours following the trauma, but with some undergoing early decompression while others presented with intracranial hypertension in a more delayed fashion. However, the authors did not identify an association between the time to surgery and survival. They concluded that the timing of surgery should be decided on an individualized basis – patients with early hypoxia and ischemia, reduced CBF, and cytotoxic edema may benefit from an early decompressive craniectomy, while those who develop reduced carbon dioxide responsivity and increased CBF 3 to 5 days after the trauma may benefit from a late decompressive craniectomy.

A more recent retrospective case-control study by Mhanna et al. [54] also explored long-term outcomes, following patients for a median of 4 years post-decompression. They reported seventeen pediatric patients with severe TBI who underwent decompressive craniectomy (all were unilateral except for one), as well as seventeen contemporarily matched patients who were managed medically. Surgery was performed a median of 2 hours after admission. In this series, decompressive craniectomy did not appear to significantly improve survival, although there was a significant effect on morbidity – the only patients to achieve a GOS score of 5 at the most recent follow-up had undergone an early decompressive craniectomy.

While many of the prior studies used survival, the GOS score, or the KOSCHI score as their primary outcome measures, the importance of quality of life (QOL), particularly with regard to neurocognitive developmental delays, has been recently emphasized. Jacob et al. [55] performed a meta-analysis of seventeen prior studies in addition to their own series of eleven patients, identifying a total of 193 pediatric trauma patients who underwent decompressive craniectomy and had at least 6 months of follow-up. The authors converted the GOS scores at 6 months to parametric measures of utility or health-related QOL. They found a pooled mean mortality at 6 months of 20.3%. However, the pooled mean QOL among those who survived was 0.723, which translates into a QOL that is 72% of the value of a normal state of health. Sixty percent of all of the included patients had a favorable outcome at 6 months; when only those patients who survived were considered, 78% had a favorable outcome. The authors therefore concluded that despite a mortality rate of 20%, children who survive 6 months following a decompressive craniectomy for refractory intracranial hypertension can be expected to function independently.

In another retrospective review, Pérez Suárez et al. [56] placed a particular emphasis on psychiatric disorders and academic performance following decompressive craniectomy. They reported fourteen patients with a mean age of 5.5 years, four of whom underwent decompressive craniectomy due to refractory intracranial hypertension, while ten underwent early surgery due to clinical and radiographic findings that were compatible with herniation. Twelve of the patients underwent unilateral parietotemporal hemicraniectomy and duraplasty, while two patients underwent bifrontal craniectomy with bilateral duraplasty. Two patients (14%) died, but all of the survivors had functional independence (GOS of 4 or 5) after 2 years of follow-up. Nevertheless, many of the patients experienced psychiatric and/or academic complications. At a mean follow-up of 3.2 years, two patients were diagnosed with attention-deficit/hyperactivity disorder, three had issues with aggressiveness, one had oppositional defiant disorder, and three required psychiatric care. Four patients had good academic performance, six patients had acceptable performance but required support, and an additional two patients needed to have their curriculum adapted because of a low intelligence quotient.

Academic performance following decompressive craniectomy was also explored by Güresir et al. [57]. Among a series of thirty-four pediatric patients who underwent a decompressive craniectomy, twenty-three were TBI patients, all of whom presented with a GCS score of 3 and were taken to the operating room immediately. Within the TBI cohort, 30% of the patients did not graduate from school, but one patient achieved a 9th grade education, five achieved a 10th grade education, and one patient became eligible for university. In an attempt to identify predictors of outcome, the authors performed a systematic review of 172 pediatric patients who underwent decompressive craniectomy. Overall, 62% of the patients had a favorable outcome after at least 6 months (69% in the non-trauma cohort versus 60% in the trauma cohort). There was no relationship between age or timing of surgery and outcome, and while unilateral and particularly bilateral mydriasis seemed to predict a poorer outcome, the differences did not reach statistical significance. In fact, a multivariate regression analysis found that a non-traumatic indication for decompression was the only variable that was significantly associated with a favorable outcome.

COMPLICATIONS OF DECOMPRESSIVE CRANIECTOMY IN THE PEDIATRIC POPULATION

Among pediatric patients, decompressive craniectomy is associated with many of the same complications as in adults, although the prevalence varies based on age. Hydrocephalus and subdural hygromas are the most common complications, with clinical series finding an incidence of post-surgical hygroma as high as 62% to 83% [56, 58]. Infants, in particular, have been hypothesized to have a higher rate of subdural collections following trauma due to the presence of a permeable dural venous plexus, which is thought to have a role in CSF resorption until the arachnoid granulations mature. According to this hypothesis, a large duraplasty using an allogenic graft impairs the ability of the native dura to resorb CSF, and subsequently allows CSF to collect in the subdural space. Posttraumatic hydrocephalus can further exacerbate the subdural collection by “feeding” it through a posttraumatic or post-surgical arachnoidal tear [59]. Alternatively, blood-brain barrier disruption and/or abnormal CSF flow dynamics may occur after trauma, surgery, or both, contributing to the pathophysiology of both hygroma and hydrocephalus [58].

Figure 4. A lateral 3D reconstruction (left) and an axial bone window (right) of a CT scan demonstrating bone flap resorption in a 17-year-old boy with a right MCA infarct who underwent decompressive craniectomy and subsequent cranioplasty 2 months later. (Courtesy of M Groves, University of Maryland).

Bone flap resorption following cranioplasty is another significant issue seen in pediatric patients undergoing decompressive craniectomy, occurring at much higher rates than in adults (see Figure 4). Particularly in pediatric patients, replacement of the original bone that was removed during the decompression has typically been advocated in order to allow the bone to become reintegrated and grow with the patient, as well as to avoid the introduction of a foreign body [60]. The bone flap is routinely cryopreserved; although subcutaneous storage of the bone in an abdominal pocket is an option for adults, it is typically not recommended in pediatric patients, particularly infants and young children, given the large head-to-body ratio and the surgical trauma that would be required to create an adequate abdominal pocket [59]. Unfortunately, upon replacement of the bone flap, many pediatric patients experience resorption of the bone over time, with Piedra et al. [61], Gruber et al. [62], Grant et al. [60], and Bowers et al. [63] reporting resorption rates of 29.5%, 33.3%, 50%, and 50%, respectively. These rates are higher than those reported for other elective pediatric cranial procedures [64].

There are various explanations for the high rate of bone resorption in pediatric patients undergoing decompressive craniectomy and subsequent cranioplasty. Successful reintegration of an autologous cranioplasty requires bone revascularization, osteoconduction, osteoinduction, and osteogenesis [59]. Freezing the bone flap was originally thought to contribute to the risk of resorption, as the cryopreservation process was thought to impact the osteoconductive potential of the bone [65, 66]. However, the results of more recent studies seem to suggest otherwise [67]. Additionally, this would not explain the higher rate of bone resorption in pediatric patients relative to adults. Intrinsic anatomical and physiological features of pediatric patients, however, may also play a role. In particular, children have inherently thinner skulls and undergo naturally high rates of bone turnover, potentially contributing to the incidence of bone resorption [60, 67, 68]. Moreover, preclinical data suggest that the growing brain places mechanical, tensile strain on the overlying immature dura, which induces the secretion of growth factors that contribute to osteogenesis, particularly during the first 2 years of life [59, 69, 70]. Expansile duraplasty, in which a large segment of the brain is covered with an artificial dural replacement, may interrupt the physiological interactions between the brain, the native dura, and the overlying bone, and the subsequent lack of growth factor secretion may contribute to bone flap resorption. Similarly, the presence of a ventriculoperitoneal shunt may also blunt the natural ICP fluctuations that contribute to skull growth, resulting in a higher rate of resorption in shunted patients [63].

Several groups have identified specific risk factors for bone flap resorption in pediatric patients. Grant et al. [60] found that the size of the craniectomy was a significant factor, concluding that bone flaps larger than 75 cm² were more likely to undergo resorption (60% versus 0%). Piedra et al. [61], on the other hand, identified a freezer time of more than 6 weeks as the only significant risk factor for resorption (42% versus 14.3%). In a study of fifty-four patients who underwent cranioplasty following decompressive craniectomy for TBI, Bowers et al. [63] found that 50% of the patients experienced bone flap resorption at an average of 4.8 months following replacement. They identified several independent risk factors for resorption, including underlying contusion, a permanent ventriculoperitoneal shunt, and age less than or equal to 2.5 years. In general, revision cranioplasties were quite successful with close to an 85% success rate, although synthetic bone flap replacements (including polyetheretherketone synthetic flaps) were found to be more successful than autologous split-thickness bone grafts.

GUIDELINES FOR THE ACUTE MEDICAL MANAGEMENT OF SEVERE TRAUMATIC BRAIN INJURY IN INFANTS, CHILDREN, AND ADOLESCENTS: THE ROLE OF DECOMPRESSIVE CRANIECTOMY

Given the variable practices, outcomes, and complication rates reported in the literature, over the years the need for evidence-based guidelines became clear. The first edition of the “Guidelines for the Management of Severe Head Injury” was published in 1996 and represented an effort by the Brain Trauma Foundation, the American Association of Neurological Surgeons, and the Congress of Neurological Surgeons to collate the existing literature and develop evidence-based recommendations for the management of adults with severe TBI [24]. Unfortunately, the guidelines did not specifically address pediatric patients. Therefore, participants of the 5th Annual Aspen Neurobehavioral Conference in March 2000 initiated a multidisciplinary task force to adapt the adult guidelines, developing a set of key topics pertaining to the management of patients younger than 18 years old with severe TBI. Classifying the evidence as Class I (randomized controlled trials), Class II (prospective studies or retrospective studies based on reliable data), or Class III (retrospective data in the form of clinical series, case reports, or expert opinion), the authors developed a set of standards (high degree of clinical certainty), guidelines (moderate degree of clinical certainty), and options (unclear clinical certainty), which were published in 2003 as the “Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents” [71].

Upon reviewing the literature from 1966-2001, the authors determined that none of the topics had sufficient evidence to support a standard. However, a number of guidelines and options were promoted, and a critical pathway for the treatment of established intracranial hypertension was developed by committee consensus. In particular, ICP monitoring was determined to be an option in infants and children with a GCS score less than or equal to 8, regardless of whether the fontanelles and sutures are open. ICP monitoring may also be considered in patients with mild or moderate TBI who have mass lesions, or in patients who cannot undergo serial neurological examinations because of sedation. Furthermore, the panel determined that an option for the treatment of intracranial hypertension is to initiate treatment at an ICP greater than or equal to 20 mm Hg, although they noted that this should be considered within the context of the neurological exam, other physiologic parameters, and imaging findings. A number of treatments for intracranial hypertension were explored, including decompressive craniectomy. The authors presented decompressive craniectomy as an option for the treatment of pediatric patients with severe TBI, diffuse cerebral swelling, and refractory intracranial hypertension, particularly in patients who presented with abusive head trauma. Patients with “potentially recoverable” injuries who developed a secondary clinical deterioration and/or an evolving cerebral herniation syndrome within the first 48 hours following the trauma were promoted as a particularly favorable group. In contrast, patients whose GCS score was never better than 3 and those with sustained ICPs greater than 40 mm Hg prior to surgery were felt to be poor candidates for decompression.

These guidelines were updated in a second edition that was published in 2012 (see Table) [34]. The panel identified twenty-seven new studies that had been published since 2003 and utilized more rigorous inclusion criteria, resulting in the exclusion of twenty-five publications that had been included in the initial set of guidelines. Furthermore, the recommendations in

the second edition of the guidelines were presented as Level I, II, and III recommendations, rather than standards, guidelines, and options. The authors provided Level III recommendations simply stating that the “use of ICP monitoring may be considered in infants and children with severe TBI” and that treatment of ICP may be considered at a threshold of 20 mm Hg. However, the authors admitted that treatment may need to be individualized in certain circumstances, and that in particular the need for age-adjusted ICP thresholds requires further investigation. Unlike the first edition of the guidelines, the authors of the second edition concluded that there was insufficient evidence to determine patient characteristics that are predictors of outcome following decompressive craniectomy. Instead, the panel provided a Level III recommendation that “decompressive craniectomy with duraplasty, leaving the bone flap out, may be considered for pediatric patients with TBI who are showing early signs of neurologic deterioration or herniation or are developing intracranial hypertension refractory to medical management during the early stages of their treatment” [34].

The first and second editions of the Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents provided an evidence-based framework for the management of pediatric patients with severe TBI, and recent literature has established that the guidelines are effective. A retrospective study performed at five regional pediatric trauma centers confirmed that a set of sixteen acute care clinical indicators of adherence to the 2003 guidelines during the first 72 hours following admission resulted in improved survival at discharge and improved neurological outcome on follow-up [72]. Unfortunately, though, many of the recommendations in the guidelines were at the “option” or “Level III” level, and there has been substantial variability in institutional adherence to the guidelines. An analysis of the American College of Surgeons National Trauma Databank from 2002–2008 identified 7,140 pediatric patients with moderate or severe TBI who were hospitalized at 156 individual hospitals and found significant patient, hospital, and regional variability with regard to the decision to perform ICP monitoring and/or decompressive craniectomy [73]. The Pediatric Guideline Adherence and Outcomes (PEGASUS) project has attempted to track and study these variations in adherence to the evidence-based guidelines [74]. With an improved understanding as to what drives adoption of the guidelines, the investigators of the PEGASUS project hope to ultimately improve adherence and thereby optimize patient outcomes.

Table 1. Summary of 2012 guidelines for the use of decompressive craniectomy in the management of pediatric TBI patients

Topic	Level III Guideline
Indications for ICP monitoring	Consider in pediatric patients with severe TBI
Threshold for treatment of ICP	Consider treatment at a threshold of 20 mm Hg
CPP thresholds	- Minimum CPP 40 mm Hg in children with TBI - Consider a threshold of 40-50 mm Hg - There may be age-specific thresholds
Decompressive craniectomy	- Decompressive craniectomy with duraplasty, leaving the bone flap out, may be considered for: - Early signs of neurologic deterioration or herniation - Refractory intracranial hypertension during early stages of treatment

FUTURE DIRECTIONS

While the publication of the Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents represented a significant step in formulating evidence-based recommendations for the management of this complex patient population, the guidelines have also highlighted how much work is still left to be done. In particular, further studies are needed to determine whether age-specific guidelines are necessary, especially with regard to the use of age-dependent ICP thresholds. Additionally, to date a prospective randomized trial has not been performed to evaluate the more common decompression techniques, i.e., unilateral fronto-parietotemporal craniectomy and duraplasty or bifrontal craniectomy and duraplasty, specifically in pediatric patients. Nevertheless, the recently published RESCUEicp trial included patients as young as 10 years of age, and a subgroup analysis of the pediatric patients would be valuable [75].

Moving forward, a primary challenge for TBI researchers and clinicians remains the relatively low numbers of pediatric patients who present to individual centers with severe TBI. Consequently, there is now a growing recognition that in order to analyze a large enough sample size, multi-center collaborations are critical. A second option involves the use of prospective pediatric TBI databases and registries, which would allow the statistical analysis of observational data involving large cohorts. To this end, the National Institute of Neurological Disorders and Stroke has completed a comprehensive effort to develop “common data elements” for pediatric TBI [76, 77]. These data elements will allow more uniform data to be collected across centers, enabling data from different studies to be compared more effectively or combined in meta-analyses. While there are still many unanswered questions, future studies with expanded datasets may ultimately lead to more nuanced management guidelines and higher levels of evidence for the use of decompressive craniectomy in pediatric TBI patients.

ABSTRACT

Bomb blast causes severe multiple trauma and distinctive patterns of head and neck injury. Brain swelling, hemorrhage, and penetrating metal and bone fragments with intracranial air are typical, resulting in severe intracranial hypertension. Decompressive craniectomy has become a mainstay of treatment for blast and missile penetrating injuries of the brain occurring in modern warfare. The clinical management and the surgical techniques for these injuries are directly transferable to the management of civilians injured by bomb blast during terrorist attacks in countries where wars are not being fought. We therefore strongly recommend that civilian neurosurgeons become familiar with the resuscitation, assessment, investigation, and surgery required to treat these injuries.

Keywords: decompressive craniectomy, blast injury, penetrating brain injury, military surgery, gunshot wound

INTRODUCTION

The wars on terror in Iraq and Afghanistan (Operation Iraqi Freedom [OIF] and Operation Enduring Freedom [OEF], respectively) followed the horrendous terrorist attacks on the United States of America on September 11, 2001. The improvised explosive device (IED) became the weapon of choice for the enemy fighters and terrorists (including suicide bombers) in Iraq and Afghanistan. Bomb blasts have caused many military and civilian casualties in these wars and in terror attacks on civilians around the world [1-3]. Casualties with extensive multisystem injuries, called “polytrauma”, have resulted. The four main types of trauma caused by these bomb blasts have been extensively reviewed and consist of combinations of primary blast injury, fragmentation injury, displacement injury from persons or objects being thrown by the blast, and miscellaneous injury including burns that may affect the face, scalp, and respiratory tract [4, 5].

Trauma to the head and neck has been a common site for injury following exposure to bomb blast [6, 7]. After the terrorist bombing in Madrid in 2004, 52% of victims sustained head trauma [2]. In terror-related incidents, secondary fragments injured the face in 49.5% of casualties, the head in 33.7, and the neck in 13% [3].

Military neurosurgeons have treated many victims of bomb blast in the past 15 years and have gained much experience in how best to treat these complex injuries [5, 6, 8, 9]. These bomb blast injuries are frequently associated with gross brain swelling, hemorrhage, and raised intracranial pressure. Penetration of bomb fragments into the brain adds further complexity to these injuries.

Penetrating brain injuries due to high-velocity military rounds have also been frequently encountered in modern war zones. These missiles also cause extensive trauma with hemorrhage and gross brain swelling. The management of these injuries frequently requires decompressive craniectomy [10]. Gunshot wounds to the head are also frequently encountered by neurosurgeons in civilian hospitals [11].

Early extensive decompressive craniectomy has become a mainstay of treatment for soldiers thus injured and has also been of advantage for the safe evacuation of the casualty to more advanced levels of care. Decompressive craniectomy allows for maximal intracranial pressure (ICP) control during long medical flights to more advanced care [12]. Tension aerocele is also prevented in flight. Injured in-country personnel or civilians who have had decompressive craniectomy can then be transferred to the local health facilities, which may lack the expertise or equipment to manage elevated ICP [12].

Although more extensive debridement for the management of ballistic head trauma was performed by some neurosurgeons in the Vietnam war [13] and the Iran/Iraq war [14], other neurosurgeons in the Israel/Lebanon war [15] and the Iran/Iraq war [16] have advocated less extensive debridement. The surgical management of blast and missile penetrating head trauma in OIF/OEF has become more extensive than in previous wars. This more recent trend for more extensive surgery has resulted, first, from the substantial injury caused by close exposure to the bomb blast versus more focal shrapnel or bullet injury; second, from high quality prehospital care that results in survivors with more severe injuries; and third, from the proximity of neurosurgeons to the battle zone.

Unfortunately, terrorist attacks resulting in mass casualties due to bomb blast have become more common throughout the world [17]. We strongly recommend civilian

neurosurgeons become familiar with the management of blast and penetrating injuries including the surgical techniques for decompressive craniectomy. Extensive decompressive craniectomies have become standard practice for these injuries.

The decompressive craniectomy randomized clinical trial for diffuse brain injury with intracranial hypertension (DECRA) was conducted on a select group of patients with blunt traumatic injuries and diffuse symmetrical swelling of the hemispheres without intracranial hemorrhage [18]. This trial and the subsequent RESCUEicp trial [19] do not apply to the management of military neurotrauma due to bomb blast or penetrating injury to the head. The pathophysiology of blast injury and penetrating injury (see below) is different from blunt injury and diffuse axonal injury caused by deceleration in motor vehicle accidents, falls, sport injuries, and assaults. Patients with blast and penetrating injury were not included in these two trials.

HISTORY OF CRANIOTOMY/CRANIECTOMY FOR PENETRATING AND BLAST INJURY

The history of military cranial surgery for penetrating injury has been extensively reviewed [20]. In 1908 Cushing described subtemporal decompression for the intracranial complications associated with bursting fractures of the skull [21]. Cushing advanced military neurosurgery during his service on the Western Front in the first World War (WWI). He advocated en bloc removal of involved bone, aggressive debridement of the brain, and extraction of bone fragments [20, 22]. Both Cushing and Horrax emphasized additional perioperative procedures including shaving the scalp, patient positioning, and overall aseptic technique [20]. Cushing also advocated water-tight closure of the scalp, a procedure that was not universally practiced during WWI [23]. Cushing was influenced by the previous experience of other surgeons in WWI [23].

Advances in resuscitation, anesthesia, surgical technique, antibiotics and infection treatment, seizure prophylaxis and management in subsequent wars informed civilian practice [20, 24-27]. The US Army Medical Service *Neurological Surgery of Trauma* published in 1965 recommended exposure of 4 cm of bone around a fracture site and en bloc excision of the fracture and removal of in-driven bone fragments [28]. However, extensive decompressive craniectomy for blast and penetrating brain injuries was not a feature of surgery in WWI or the second World War (WWII). Casualties received early neurosurgery in forward hospitals in WWI, WWII, and the Korean War [20, 27, 29]. Early evacuation by helicopter in the Vietnam War enabled casualties to receive early neurosurgery. Rish et al. advocated craniotomy as a debridement technique for penetrating cranial trauma in Vietnam [30].

Less extensive surgery was practiced in the Israel-Lebanon war, informed by early computed tomography (CT) scan for the first time in modern warfare [15]. No attempt was made to remove in-driven fragments of bone or metal. Minimal debridement was also practiced in the Iran-Iraq War [16]. These injuries tended to be low velocity fragment injuries rather than the diffuse blast seen in OIF/OEF. Also, CT was able to identify those with hematomas or later infection who needed more extensive surgery. CT brain scans were also used to help guide surgery in Operation Desert Storm in 1991 [31].

Kjellberg and Prieto described bifrontal decompressive craniotomy for massive cerebral edema in 1971 [32], and Polin et al. described decompressive bifrontal craniectomy for severe refractory posttraumatic cerebral edema in 1997 [33]. Decompressive craniectomy became extensively used in severe blunt traumatic brain injury (TBI) in the 1980s and 1990s to treat brain swelling, acute subdural hematoma, and intracranial hypertension. Unilateral craniectomy was most often used. Hemicraniectomy was also found to be of benefit for malignant middle cerebral artery territory infarction [34, 35]. This experience from civilian neurosurgery influenced the practice of military neurosurgery for blast injury.

From the Iraq and Afghanistan wars of the 1990s to the present, use of more powerful bombs and IEDs has increased with soldiers frequently being close to the epicenter of the blast, either mounted in vehicles or dismounted on patrol. The basic science and pathophysiology of blast and penetrating injuries was better understood than in previous wars. Survival from these severe blast injuries has improved because of immediate resuscitation by skilled combat medics in the field, rapid evacuation to far-forward combat support hospitals for further resuscitation and initial wound surgery, and early evacuation to in-theater advanced field hospitals where neurosurgery and other specialty surgery is performed. More extensive craniofacial injuries due to bomb blast were also encountered by military neurosurgeons in OIF/OEF. A more aggressive approach to the head and neck injury and the other extensive injuries was required to save lives and obtain the best outcomes. All of this civilian and military surgery experience combined to encourage neurosurgeons in OIF and OEF to perform more extensive decompressive craniectomy in the acute military setting [8, 9].

Figure 1. Axial CT brain scan of a bomb blast injury showing multiple fragments of metal that have entered from the left parietal region, associated generalized brain swelling, patchy small hemorrhages, and bubbles of air. Note the fractures in the skull on the left side and the gross scalp hematoma/swelling. (Courtesy of J Rosenfeld, Monash University).

Figure 2. Axial CT brain scan of a bomb blast injury showing basal subarachnoid hemorrhage. Note the two metal fragments on the right side in relation to the circle of Willis. The patient requires an angiogram (CT or digital subtraction angiogram if available). (Courtesy of J Rosenfeld, Monash University).

From 2007 to 2009, two hundred ten neurosurgical procedures were performed at the US Hospital at Bagram, Afghanistan. Ninety were craniotomies for wartime trauma including twenty-eight decompressive craniectomies (31% of craniotomies) in twenty-seven patients. Twenty-four of twenty-eight (86%) were unilateral frontotemporal, seven of twenty-eight (25%) were bifrontal, and two of twenty-eight (7%) were suboccipital. Nineteen of these were performed for penetrating injury (gunshot wound = 13; explosions = 6) and nine for severe closed head injury (explosions = 6; motor vehicle crash = 2; fall = 1) [12].

PATHOPHYSIOLOGY OF BLAST INJURY TO THE BRAIN

The wide spectrum of injury to the brain, head, and neck caused by bomb blast ranges from mild concussion to severe life-threatening or non-survivable trauma [36, 37]. The extent of injury depends on the distance of the victim from the epicenter of the blast, whether the victim is in an enclosed or open space, whether the victim is wearing head protection with a helmet and ballistic eye protection, and the position and body disposition of the victim (standing or horizontal). The pathophysiology of blast injury to the head has been studied extensively in rodent and pig models [38].

Figure 3. Axial CT brain scan of a bomb blast injury showing multiple fragments of metal, intracerebral hemorrhage, and generalized brain swelling. (Courtesy of J Rosenfeld, Monash University).

Figure 4. Axial CT brain scan of a bomb blast injury following decompressive craniectomy showing brain edema and herniation at the craniectomy site. (Courtesy of J Rosenfeld, Monash University).

Figure 5. Operative photograph showing the gross brain swelling and vascular engorgement caused by bomb blast. (Courtesy of J Rosenfeld, Monash University).

The over-pressure waves generated from the bomb blast epicenter result in shock waves that pass through the skull, skull orifices, and brain and reflect off the inside of the skull to magnify the effect. The physics of blast injury is complex and multifaceted [6]. There is diffuse brain swelling, diffuse axonal injury, and combinations of intracranial hemorrhage including epidural, subdural, subarachnoid, intracerebral, and intraventricular. The brain edema is often severe and results in life-threatening intracranial hypertension. See Figures 1–5.

This pathology is compounded by penetrating metal fragments of bomb and skull bone fragments, often with dirt, fragments of clothing, skin, and hair entering the brain in addition to the metal. These penetrating wounds are heavily contaminated. The trajectory of fragments may pass from below through the facial skeleton, orbits, or posterior fossa or lower temporal zone into the brain. Complex calvarial compound depressed fractures and basal fractures with cerebrospinal fluid (CSF) leaks result [5, 6, 10]. Pseudoaneurysms and vasospasm develop in a significant number of severe blast TBI victims and may cause delayed deterioration [39, 40]. The eyes and ear drums, ossicles, cochlea, and vestibular organs may also be injured. The structures in the neck are also vulnerable, namely, the pharynx, larynx, carotid and vertebral arteries, spine, and spinal cord.

Facial and/or orbital injuries may extend to skull base fractures. Extension into the sphenoid wing or body is not uncommon. When these skull base fractures occur, there is a higher likelihood of carotid artery injury, with pseudoaneurysm, dissection, and carotid cavernous fistula. Other injuries are CSF fistula through fractures in the frontal, sphenoid, and/or ethmoid sinuses with delayed meningitis, cranial nerve palsies (I, II, III, IV, V, VI), and frontal encephaloceles through defects in the skull base. Both carotid cavernous fistula and encephalocele can result in pulsatile proptosis. The extension of facial/orbital injuries into the sphenoid bone can be identified on bone windows of the CT scan and proximal carotid injury can be identified on CT angiogram.

Paradoxical brain herniation could occur following a decompressive craniectomy if there is ongoing CSF leak through the skull base fractures. This creates a downward pressure gradient with atmospheric pressure acting on the brain from above and the CSF leak lowering the intracranial pressure from below.

High velocity missile or projectile penetrating injury involves direct pressure effects of the projectile, and cavitation of surrounding brain with resultant intracerebral hemorrhage and brain swelling are both quite different from blunt injury and diffuse axonal injury caused by deceleration [10, 41].

ACUTE MANAGEMENT

We have previously described the management of penetrating injury to the head including blast injury [5, 10]. The early surgery for severe trauma should follow the principles of “damage control surgery” with vigorous resuscitation, rapid access to the operating room, abbreviated surgery, and continued correction of physiological derangement to prevent the lethal triad of acidosis, coagulopathy, and hypothermia. The term *abbreviated surgery* was originally used to describe trauma laparotomy with rapid control of bleeding and hollow viscus contamination of the peritoneal cavity. “Damage control” principles also apply to emergency neurosurgery where emergency decompressive craniectomy has a role in the management of blast injury to the brain [42]. Importantly, “abbreviated” in the context of neurosurgery indicates being time efficient, but does not mean insufficient. Taking short-cuts, such as leaving the dura open, may result in serious preventable morbidity. Neurosurgery can be both meticulous and abbreviated.

Battlefield resuscitation has advanced considerably in the past decade and has been informed by a growing evidence base [43]. A highly efficient military trauma system that delivers early advanced care to the injured soldier has saved many lives and has been translated to the civilian trauma system. Evidence has been generated from extensive battlefield experience and collated and analyzed from the Joint Theater Trauma Registry of the US military. Guidelines have been prepared and published in the *Journal of Trauma* and online [44-48].

Triage and Initial Resuscitation

The casualty should be rapidly triaged by an experienced trauma specialist. Decisions are made to provide immediate, urgent, or delayed treatment.

The principles of resuscitation are to stop hemorrhage, prevent hypoxia and hypercapnia, and correct shock/hypotension. The principles of “damage control resuscitation” follow from these goals [43]. Blood is cross-matched and blood clotting checked. A well-prepared trauma team carries out “horizontal” simultaneous procedures and treatments rather than a “vertical” step-by-step protocol. Major bleeding is controlled with tourniquets to the limbs and/or direct pressure dressings and manual compression. An airway is rapidly secured. A brief neurological assessment is made, including Glasgow Coma Scale (GCS) score, pupil size and reactivity, and weakness in the limbs (hemiparesis, quadriparesis, or paraparesis before the

patient is sedated or anesthetized). If the GCS score is <9, an endotracheal tube should be placed using a crash induction technique to prevent laryngeal spasm, straining, coughing, and jaw clamping, which will cause secondary rises in intracranial pressure. If there is severe facial trauma or facial /respiratory tract burns, the casualty will require an urgent endotracheal tube before swelling and/or hemorrhage compromises the visualization of the larynx. For those with severe facial trauma or facial burns, the endotracheal tube is converted to a tracheotomy at the commencement of the operating room procedures.

For patients with severe TBI and polytrauma, resuscitation should be directed at achieving adequate cerebral perfusion and correcting coagulopathy and other physiological derangements. A target systolic blood pressure should be based on that required to achieve adequate cerebral perfusion pressure. Blood component replacement (hemostatic resuscitation) should be started early, especially when there is severe cranial penetrating injury. A 1:1:1 ratio of plasma, platelets, and red cells is an effective strategy to correcting coagulopathy of trauma [49]. The casualty should be kept warm with a thermal blanket to prevent hypothermia.

Medication

Prophylactic broad spectrum antibiotics and tetanus prophylaxis are administered [47]. We currently recommend intravenous vancomycin and meropenem prophylaxis for blast and penetrating cranial trauma in war zones because of the heavy contamination of these wounds. Prophylactic anticonvulsants are administered with an intravenous loading dose of phenytoin or levetiracetam. Intravenous mannitol or hypertonic saline may be administered as a temporizing measure if there are signs of deteriorating neurological status while the casualty is awaiting surgery. Steroids are not indicated.

Imaging

There is almost always time to get a CT of the head and neck prior to surgery unless the patient is exsanguinating. In that case, the patient should be taken straight to the operating room. With penetrating injury to the brain or concern about a possible vascular injury, a CT angiogram should be obtained at the time of the CT. An urgent chest radiograph is obtained in the emergency room by mobile x-ray machine. The neurosurgeon should identify injuries to facial skeleton, orbits, sinuses, and skull base. These injuries will need attention during the first operation. The general surgeon may require CT of chest and abdomen with or without pelvis, and the orthopedic surgeon may require some limb radiographs. The time taken to get images should be kept to a minimum.

When a casualty has polytrauma, combined simultaneous surgery may be required to achieve the goals of rapid damage control surgery. For example, the orthopedic and vascular surgeons are debriding and stabilizing a penetrating limb wound with compound fracture and vascular injury, the general surgeon is performing a laparotomy, and the neurosurgeon is performing a decompressive craniectomy. This scenario has been common in military settings but should also be adopted in the civilian setting [50]. The decompressive craniectomy should

not wait until the end of a laparotomy because the brain may suffer ongoing injury from continuing intracranial hypertension during this time.

Acute Management of Accompanying Injuries

The patient's eyes are closely inspected for globe penetration or hyphema before the lids become difficult to open due to swelling. A lateral canthotomy may be required to relieve gross orbital swelling. Fragments of metal in the eyes can be identified on the CT head scan. The external auditory canals are inspected for drum perforation and the presence of blood/CSF in the canals. Severe penetrating injury to the face and sinuses causes profuse hemorrhage and rapid swelling of the tissues. Local packing is placed to quell the hemorrhage until repair is undertaken. Facial and sinus injuries should be addressed early if the surgeon has the skill and resources (see below).

INDICATIONS FOR DECOMPRESSIVE CRANIECTOMY

A serious blast injury to the head will result in significant brain swelling and intracranial hypertension. Decompressive craniectomy is indicated for this injury. There are three types of decompressive craniectomy and the indications for each type depend on the pattern of injury.

Unilateral Decompressive Craniectomy (Hemicraniectomy)

The blast or missile penetrating injury is predominantly on one side of the brain with unilateral hemisphere swelling and midline shift to the opposite side. This is frequently accompanied by acute subdural or epidural hematoma. Penetrating injury may also be present on that side.

Bifrontotemporal Decompressive Craniectomy

The indications are bilateral symmetrical hemisphere swelling/contusion, bifrontal injury, transventricular fragment or missile trajectories. This approach also gives access to the floor of the anterior cranial fossa if there are complex anterior skull base fractures over the orbits and ethmoid and frontal sinuses.

Posterior Fossa (Suboccipital) Decompressive Craniectomy

Indications are penetrating injury to the posterior fossa with extra-axial hemorrhage or hemorrhage/swelling in the cerebellum. If the brain stem is involved in the trajectory of a fragment or bullet, the prognosis may be very poor and decompression is not likely to improve outcome [10].

Penetrating injury across the area of brain 4 cm above the dorsum sellae or “zona fatalis” (midline skull base, thalamus, brainstem) is usually fatal and decompressive surgery is not performed [51].

OPERATIVE SURGERY

The principles developed in OIF/OEF have combined minimal debridement with maximal bone removal [12]. The key objective with any decompressive craniectomy for trauma, especially blast injury, is to make it as large as possible. If the craniectomy is too small, the swollen brain herniates over the bone at the edges and lacerates or strangulates, becoming ischemic or infarcted. The surgical technique for unilateral and bilateral decompressive craniectomy has been well described [12, 52].

Scalp

The scalp should be completely shaved. The three-pin neurosurgery operating table head clamp is applied if available, otherwise the head is placed on the horseshoe rest. Care is taken to place the pins away from where the scalp incision will be made. The ipsilateral shoulder is raised if the head is in a lateral position. The head of the table is elevated 10 degrees.

Three types of scalp incision can be used when performing DC for military trauma:

1. A midline sagittal incision with a “T-bar” incision was described by Ludwig G. Kempe for hemispherectomy [53]. The midline incision extends from the hairline to the inion. The T-bar incision starts 1 to 2 cm anterior to the tragus at the root of the zygoma and extends superiorly to meet the midline incision just behind the coronal suture. This incision preserves the superficial temporal artery and occipital artery angiosomes. The disadvantage is the tripod created at the junction of the two incisions that may necrose. The junction must be handled and sutured very carefully to avoid this problem.
2. The large reverse question mark incision starts at the root of the zygoma, posterior to the superficial temporal artery (STA), back toward the asterion, and then curves around the parietal eminence to the midline and forward to the hairline. The scalp is reflected as a myocutaneous flap with the temporalis muscle. The STA should at least be palpated and marked. A Doppler device can be used to exactly locate the STA, and the incision is kept behind the STA, which is usually 10 to 15 mm in front of the tragus.

A variation on the standard frontotemporal scalp incision is a large curvilinear C-shaped incision extending from the mastoid region behind the ear up to the midline and carried forward to the hairline if the injury has avulsed the scalp or temporalis muscle over the temporal fossa. This incision is thus separate from potentially devitalized scalp.

3. Bicoronal incision for the bifrontal craniectomy extends from the root of the zygoma, 1 to 2 cm anterior to the tragus, extending up to the midline just behind the coronal

suture and across to the other side. The surgeon should ensure that the bi-coronal incision at the vertex is at the level of the coronal suture behind the hairline. This decompresses the frontal region to the level of the coronal suture.

Late breakdown of posterior wound margins has been seen with the reverse question mark incision. This was related to compromise of the superficial temporal or occipital arteries, to the patient lying directly on the flap, and to complex scalp lacerations incorporated in the scalp flap. For this reason, surgeons in OIF/OEF tended to favor the T-shaped scalp incision, particularly when there were complex scalp lacerations [12].

Skull

The size of the initial craniectomy is of critical importance and should be carefully planned. We have seen patients for whom the extent of the injury was underestimated and the size of the decompressive craniectomy was too small.

The Guidelines for the Management of Severe Traumatic Brain Injury, Fourth Edition, recommend that unilateral frontoparietotemporal decompressive craniectomy in the civilian context be 12 cm x 15 cm diameter [54]. On the basis of their military experience, Bell et al. recommend that a hemicraniectomy for frontoparietotemporal decompression have the dimensions of at least 14 cm anteroposterior by 12 cm superoinferior [9]. The surgeon should mark the midline and the line of the transverse sinus carefully so that the bone cuts avoid the venous sinuses. The posterior bone cut should be at least 2 cm above the asterion and lambdoid suture. The craniotome is taken as low as it will go in the middle fossa, but it is important for the surgeon to use rongeurs to remove the remaining squamous temporal bone and greater wing of the sphenoid down to the floor of the middle fossa. This will decompress the temporal lobe and upper brainstem. Air cells in the sphenoid or mastoid bone must be plugged with bone wax.

For bifrontal decompressive craniectomy, burr holes are placed on either side of the sagittal sinus as well as at the pterion and at the root of the zygoma just below the superior temporal line. The posterior edge of the bone cut can extend just behind the coronal suture and extend vertically downwards to decompress the frontal and temporal lobes. The temporal bone is removed with rongeurs below the inferior cut as described in the preceding paragraph. A strip of bone can be left over the sagittal sinus to protect it. To avoid entering the frontal sinus and thus creating further potential morbidity with CSF leaks and infection, the lower bone cut can pass just above these air sinuses. This can be judged on the scout view of the CT scan or a plain radiograph if no CT is available. Cranialization of the frontal sinus will be required if the sinus is breached.

Dura

The dura should be widely opened to optimize relief of intracranial hypertension and to allow for exposure and treatment of the hematomas/penetrating injury.

For unilateral decompressive craniectomy, the dura is opened in a C shape with multiple relieving spoke-wheel cuts. The dura is cut no closer than 2 cm from the superior sagittal

sinus to avoid trauma to the sinus and bridging veins. Dural tack-up sutures are used to avoid postoperative hematomas beneath the bone edge. For bifrontal decompressive craniectomy, the dura can be opened with cuts parallel to the sagittal sinus and the posterior bone margin or with a stellate opening. Some neurosurgeons have also divided the sagittal sinus inferiorly and released the falx.

The basal dura needs to be repaired if it is lacerated. The use of a vascularized pericranial flap is preferred. This is also used to cover the cranialized frontal sinus. Tensor fascia lata can also be used. These grafts should be tacked down and can also be secured with tissue glue. Onlay graft material such as DuraGen (Integra Life Sciences Corporation, Plainsboro, New Jersey, USA) may not be sufficient for the skull base repair.

Dural expansion should be the goal for repair of the convexity dura. A duroplasty is performed with patches sewn in to create a watertight closure. In an emergency situation, however, a dural substitute such as DuraGen is laid over the dural openings. This does not require suturing and is quickly applied. In blast and penetrating injuries, a watertight scalp closure is critically important to prevent CSF leak and ensure primary healing.

Bone Flap Management

For bone flap management, surgeons have the following four options:

1. In Afghanistan and Iraq because of the high levels of contamination of the bone encountered in the complex penetrating trauma and the high risk of sepsis if the bone was replaced at a later date, the practice was to discard the bone and repair the skull with CT-derived custom-made titanium implants or 3D printed prosthetic materials such as methyl methacrylate. Bell et al. found that just over half of the military patients with severe injury to the central nervous system had concomitant systemic infections. The fluid collection around the abdominal bone implant could not be excluded as the source. The bone was discarded in almost all of these cases [8].
2. The bone can be cleaned, then washed with bacitracin or gentamicin solution, placed in a sterile plastic bag, and cryopreserved at -70°C.
3. The bone is cleaned and washed as above and placed in a subcutaneous pocket in the left lower quadrant so that the scar is not confused with an appendectomy scar in the future.
4. Hinge craniectomy can be considered, particularly in remote locations or war zones where further neurosurgery and eventual cranial reconstruction is not an option [55].

PRINCIPLES OF SURGERY FOR BLAST INJURY TO THE BRAIN

The surgery for blast injury to the brain should be rapid, but with control maintained. Large hematomas are evacuated. Devitalized tissue is debrided. Superficial debridement and irrigation of brain wounds is carried out without overly aggressive searching for deep fragments of metal or bone. Hemostasis is completed. A parenchymal ICP monitor is placed and, preferably, a ventriculostomy is also placed so that CSF can be vented to help control

ICP. The surgeon should consider removing the anterior segment of a grossly swollen damaged temporal lobe to decompress the upper brainstem. In war zones the trauma team and the neurosurgeon should also be aware of the possibility of penetrating small arms ammunition being unexploded ordnance. Special precautions will need to be taken [56].

A head and neck team consisting of neurosurgeon, maxillofacial surgeon, otorhinolaryngologist, ophthalmologist, and plastic surgeon, if available, work together to repair complex craniofacial injuries. Nasal and facial wound packing may be required to control severe hemorrhage. Although the repair of facial injuries should follow abbreviated damage control principles with limited fixation of facial fractures in the first operation, we strongly advocate adequate repair of sinus and skull base injuries at the first operation. More definitive reconstruction of the facial injuries can be pursued further during second- and third-stage surgery once the swelling has subsided.

Careful attention needs to be paid to the repair of the dura over the floor of the anterior fossa as it is frequently lacerated in these injuries. The frontal sinus requires exenteration if it is breached by the injury or by the surgeon during the opening. We recommend using pericranial vascularized flaps and autologous split thickness calvarial autograft to repair these defects. Failure to repair the skull base and sinus injuries at the first operation results in brain hernias, CSF leak, and infection. We strongly recommend against using titanium mesh for skull base repair because the mesh may eventually erode the dura and penetrate the brain or may erode the roof of the nasopharynx. Revisional surgery is rendered very challenging. The fronto-orbital bandeau is restored with autologous bone fragments, titanium miniplates, and elongated plates. This prevents brain herniation or ptosis and provides a cosmetic reconstruction of the facial contour [12]. Following the decompressive craniectomy, the scalp is closed primarily in two layers. Rotational scalp flaps may be required, if there is scalp loss, to avoid closure under tension.

CARE AFTER DECOMPRESSIVE CRANIECTOMY

Intensive Care Management

The details of intensive care management are beyond the scope of this chapter. The patient remains intubated and sedated in the intensive care unit until the ICPs are normal and the brain swelling is subsiding. This may take 7 to 10 days. The head of the bed is elevated to help control ICP. The aim is for normal physiology to be restored as quickly as possible. Rewarming continues to normothermia. Abnormal acid/base balance, coagulation, electrolytes, and hemoglobin are corrected. Early enteral feeding is commenced.

In the military setting, the casualty is evacuated by air from the frontline hospital after 24 to 48 hours and returned back to their nation by 3 to 4 days from the time of the injury [12]. The US Air Force has developed ongoing intensive care management in fixed wing transport aircraft for intercontinental aeromedical evacuation [57].

EARLY COMPLICATIONS

Postoperative hemorrhage is not uncommon and results from ongoing coagulopathy or failure to secure hemostasis at the first operation. This hemorrhage may result in an epidural, subdural, or intracerebral hematoma. A repeat scan the day after surgery or earlier if there is clinical deterioration will pick this up. Inadequate size of craniectomy will result in poor control of ICP and brain herniation with secondary injury to this extruded brain tissue. Wound ischemia or breakdown may require wound revision and avoidance of pressure on this area of scalp.

CSF leak from calvarial wounds should be prevented with dural patching and watertight scalp closure in two layers. CSF leak is not uncommon with complex skull base fractures and dural tears. CSF leak increases the risk of early and late meningitis. Revision surgery may be required to repair the leak. Lumbar drainage may be required when brain swelling subsides in order to stop the CSF leak while the tissues are healing.

Infection is a delayed complication and may require reoperation to drain subdural empyema or brain abscess. Hydrocephalus and the “syndrome of the trephined” are delayed complications that will be described in other chapters.

PROGNOSIS AFTER DECOMPRESSIVE CRANIECTOMY

The prognosis of blast and penetrating injury to the head should not be extrapolated directly from figures derived from series of patients with closed head injury, nor should the computer models of prognosis such as CRASH or IMPACT be relied upon. The outcomes of a military population with severe blast or penetrating TBI have been compared with those of a matched civilian population [10, 58].

Weisbrod et al. reported 32% of those in a combat population presenting with a GCS of 3–5 and 63% of those with GCS 6–8 achieved functional independence 2 years following severe blast or penetrating injury [59]. Bell et al. performed a retrospective study on 480 patients with head injury who presented at far-forward Combat Support Hospitals in OIF/OEF. In this population 188 decompressive craniectomies were performed: 154 for penetrating head injury, 22 for closed injury, and 12 unknown classification. Those who underwent decompressive craniectomy tended to have worse injuries with lower GCS and higher Injury Severity Score than those who did not. Glasgow Outcome Score tended to be higher in the non-craniectomy group, but those with craniectomy improved over time. At 1 year 83% had achieved a Glasgow Outcome Score greater than 3. Those with bilateral injury also on average recovered to participate in rehabilitation at 6 to 12 months [9]. Many of these soldiers would likely have died or been worse off without the decompressive craniectomy. It should also be appreciated that significant improvements in these patients may occur over 2 years, particularly with active therapy and rehabilitation.

RECOMMENDATIONS FOR TRAINING AND SIMULATION

Preparation of military surgeons and trauma teams for neurosurgical decision making and to perform selected surgical techniques including decompressive craniectomy is valuable prior to deployment [60]. Civilian general surgeons are taught the basic steps of burr hole and craniectomy/craniotomy in the Definitive Surgery for Trauma Course and practice this on cadavers, but this does not prepare these surgeons for performing extensive decompressive craniectomy.

Neurosurgeons in training would benefit from exposure to simulation models for craniectomy. Virtual reality-based simulation systems that include haptic feedback have been developed for burr holes and are being extended to intracranial hematoma craniotomy simulations [61, 62]. We await further improvements in 3D polymer printing to produce more life-like cranial simulations than those currently available. These would have all the normal layers present to give the trainee surgeon a more realistic simulation model for practice.

CONCLUSION

In wars and military conflicts, early extensive decompressive craniectomy should be considered in almost all penetrating injuries and severe closed head injuries due to bomb blast and military grade weapons. This also applies to blast injury in the civilian population resulting from terrorist attacks. Civilian neurosurgeons should become familiar with the management of bomb blast injuries.

Illustrative Case

A 16-year-old boy presented with a gunshot wound to the brain from point-blank range. There was a high left parietal entry with an anterior trajectory that carried the missile through the Sylvian fissure and exited through the frontal sinus region. The patient arrived with GCS 6T, with active brain extravasation from the exit wound. CT head scan revealed the extent of damage including significant parenchymal, probable cortical arterial, and anterior skull base, left frontal bone and frontal sinus disruption (Figure 6a, b). The key to this case was the immediate resuscitation that began upon the patient's arrival to the emergency room with 1:1:1 ratio of packed red blood cells, fresh frozen plasma, and platelets. The patient was transported to the operating room where an immediate frontoparietotemporal decompressive craniectomy was performed (minimum 15 x 12 cm) with removal of the multiple skull fracture fragments, clip occlusion of multiple bleeding middle cerebral artery vessels, exenteration and cranialization of the frontal sinus, and dural onlay with DuraGen and watertight dural closure (Figure 6c). A ventriculostomy was placed postoperatively. Early postoperative CT scans revealed the extent of initial damage and subsequent decompression (Figure 6d). Delayed CT scan revealed the residual left-sided cortical damage (Figure 6e). The patient survived, and with rehabilitation was able to ambulate and speak at the time of cranioplasty 6 months later.

ABSTRACT

Care for the severe TBI patient who has undergone a decompressive craniectomy in a war zone does not end downrange. This life saving procedure is utilized to create a window of time that will allow relatively safe transport to higher echelons of care, where further treatment, complication management, and ultimately cranial reconstruction can take place. This chapter outlines the evacuation process and highlights management issues that have been seen when treating patients that were injured during Operation Iraqi Freedom and Operation Enduring Freedom.

Keywords: decompressive craniectomy, war, Iraq, Afghanistan, military, neurosurgery

INTRODUCTION

Consideration for immediate decompressive craniectomy versus a delayed decompression depends on the early radiographic findings, mechanism of injury, patient's exam and the

¹ The views expressed in this presentation do not represent the official policy or opinion of the United States Navy, United States Army, the Defense Health Agency, the Department of Defense, or the United States Government.

environmental considerations for where the injury has occurred. In a patient subjected to a violent blast injury in an austere environment with a poor exam and radiographic evidence of diffuse edema, early decompression has been a game-changer [1]. The ability to decompress the injured hemisphere allows for a more neurologically stable patient who can then better tolerate a prolonged medical evacuation process.

This practice involves a series of carefully orchestrated events that allows a critically ill patient to be transferred along escalating levels of care. Each stage of the transfer and recovery process offers its own challenges that must be met to maximize a patient's neurological recovery. From continuing ICP management, re-exploration, vascular injury studies, hydrocephalus, infection, and ultimately cranioplasty, patients who suffer severe TBI from blast or high velocity munitions in a wartime environment are unique from their civilian counterparts [2-6]. Not necessarily in the types of issues encountered, but the degree in which they are seen.

EVACUATION OF A DECOMPRESSIVE CRANIECTOMY FROM THEATER

Once the craniectomy patient has undergone their initial medical and surgical treatment, the next question revolves around their stability to be evacuated from the theater of war. Not only does this take into account the medical/neurological status of the patient, but also the logistics of having the transport vehicle, the proper equipment, the weather, battlefield conditions, and an appropriate medical team to manage the patient during the transport process.

Depending on the location of the injury and site of initial treatment, this can involve transport by ground, helicopter, or fixed wing aircraft to higher echelons of care, ultimately back to the Continental United States (CONUS). During Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF), evacuation out of theater often meant stopping at Landstuhl Regional Medical Center in Germany prior to CONUS transport. At every stop along the evacuation route, Advanced Trauma Life Support (ATLS) protocols are followed in addition to Joint Theater Trauma System (JTTS) clinical practice guidelines, which look to build upon the management of severe head injury by applying the unique lessons learned over the years of caring for patients suffering a head injury while in a theater of war [7, 8].

During each leg of the evacuation, an Air Force Critical Care Aeromedical Transport Team (CCATT), is assigned to the craniectomy patient [9]. Developed to meet the needs of the battle-injured patient, CCATT allows en route, critical care to be delivered throughout the transport process. The average time for evacuation from the point of injury to arriving at a CONUS facility, with stops at higher echelons of care along the way, was 4-5 days during the height of OIF/OEF [9-11]. Prior to aeromedical evacuation, a unique concern that needs to be discussed with the CCATT team is the potential risk of expansion of post-operative pneumocephalus secondary to altitude. While less of a concern in a craniectomy patient given the disruption of the cranium from surgery, precautions should still be discussed [12].

Resuscitation and treatment of the patient does not stop during transport. The critical care management of a severe TBI patient, extensively defined elsewhere, is continued by the CCATT en route.[7, 8] For this patient population, given the physiological stress associated aeromedical evacuation such as hypobaric hypoxia, vibration, temperature, noise, and

altitude, a goal SaO₂ and PaO₂ of >93-95 and >80, respectively, has been set [8, 9]. Frequent documentation of the neurological exam is critical as there are multiple hand-offs by transport teams along the evacuation route.

During transport, the continuous monitoring and treatment of intracranial hypertension is critical. These patients are often intubated/sedated so an exam can be difficult to obtain. It is paramount that a working ICP monitor, preferably a ventriculostomy, is in place prior to transport, because placing or trouble-shooting an ICP monitor in flight is challenging and often the expertise is not available. Along these lines, it is better to have a monitor in place than remove it just before transport, even if ICP's have been well controlled [8]. The same logic applies to surgical drains. Medical management of intracranial hypertension in a trauma patient is maximized with the use of hypertonic agents such as 3% Saline or mannitol, head of bed elevation, sedation, paralysis, and pain control using short acting agents. An additional consideration in this patient population is to load these patients last and to off-load first, with the patient head first into the aircraft to help ameliorate the affects of relative trendelenberg position for both the take off and landing on intracranial pressure [13].

There may be times that the safest course of action for a patient with significant cerebral edema or increased ICP, despite a decompressive craniectomy, is to not evacuate them until their ICP is better controlled. As noted, there are limited treatments and few resources once the patient is en route and diverting a flight may not be an option. Given the timing of peak swelling (48-72 hours) after a head injury, it is best to do the initial decompression and transport them to LRMC or CONUS prior to this time point. Sometimes, there are patients with tenuous ICP after early decompression where a direct "tail to tail" movement is preferred, meaning they are transported directly from the theater of war to a CONUS location.

MANAGEMENT OF ICP

Classically a stepwise approach is advocated for ICP management. This includes early intubation with CO₂ control, hypertonic saline, HOB elevation, and avoiding jugular compression. If ICP remains elevated the use of a ventriculostomy is advised and could be considered if the ventricles are normal or enlarged. In those cases with slit-ventricles it may not prove worth the attempt. A ventriculostomy should be considered early unless the patient is immediately undergoing a decompressive craniectomy. Ideally decompressive craniectomy should resolve an ICP crisis. In most cases this is true, with early decompression the management of a patient's ICP is more easily controlled. The onset of delayed swelling, edema and resulting ICP elevation should be avoided with a properly performed operation. This assumes that the decompression is done in a timely manner and is large enough. A critical element is that it extends to the floor of the middle cranial fossa, and includes a large duraplasty. In those cases in which the decompression is inadequate increased ICP, cortical spreading depression and brain "fungation" out of the defect will result in further neurologic deterioration and long-term poorer outcomes [14]. Despite it being done in a timely fashion and of an appropriate size, those cases with a persistent increased ICP are usually associated with additional neurovascular injuries. Such an example includes patients with an associated thrombosis of a major dural venous sinus with inadequate collateral venous outflow. Additional examples include patient's with a markedly altered autoregulation with a passive reflection of ICP related directly to the systemic blood pressure [15]. These patients would

benefit from additional neuro-monitoring to include ICP, TCDs, Brain PbO_2 , and CBF monitoring. An autoregulation response curve can then be produced that evaluates CBF/MAP and ICP over a range of values and in response to various CO_2 values. In those rare cases in which ICP is persistently elevated due to a major cortical vein thrombosis or a dural sinus thrombosis then other strategies should be employed. If the patient has already undergone a decompressive craniectomy then consider the role for a neurointerventional thromboaspiration of the occluded sinus. In the face of a decompressive craniotomy with normal venous outflow and persistently elevated ICP consider the additional use of induced hypothermia and/or pentobarbital coma or in rare cases both. The temporary use of these adjuncts will allow for the re-establishment of autoregulation, controllable ICP management.

DELAYED MANAGEMENT: HYDROCEPHALUS/ SYNDROME OF THE TREPHINE

Once patients have undergone decompressive craniectomy they are vulnerable to a variety of CSF and pressure disturbances. These include delayed hydrocephalus, “sinking scalp syndrome”, and external hydrocephalus/hygromas [16-19]. It is unclear which patient’s are likely to develop which complication, as it is a matter of time, size of decompression and volume of underlying brain injury. Different theories exist to explain CSF disturbance but remain conjecture as proving the etiology in-vivo is clouded by multiple variables. One of the strongest theories places the development of hydrocephalus as a compensation for the collapse of the subarachnoid spaces and atmospheric pressure displaced on the dural venous sinus and large cortical veins. The resulting effect is postulated to be an increased “windkessel” effect from the arterial pulse-pressure displaced to the brain [20]. As a result the anterior choroidal artery and the choroid plexus has increased amplitude of pulsations. These pulsations are then dampened by the expansion of the ventricles as atmospheric pressure effects on the open hemicranium usually collapse the subarachnoid space. In some of these cases reconstructive cranioplasty alone without shunting resolves the hydrocephalus. However, in those with significant volume loss from underlying brain injury shunting is required. In such a case the combination of shunting with a hemicraniectomy results a significant exacerbation of the syndrome of the trephine. Collapse of the cortical mantle, overlying scalp and ventricular system may exacerbate the underlying neurologic dysfunction with a paradoxical mid-line shift, and downward herniation of the diencephalon. It has been our experience that the use of programmable valves, anti-siphon devices, abdominal binders, trendelenburg position, and hydration help to mitigate this effect [21]. Typically, the symptoms are improved only after reconstruction of the cranial vault. Restoring normal physiology with a closed cranial vault allows the cortical mantle to re-expand, subarachnoid space to be restored and its damping effect of the CSF to occur.

DELAYED MANAGEMENT: CEREBROSPINAL FLUID LEAK

Severe blast and ballistic injuries can affect the skull base and lead to sub-acute or delayed CSF leaks, encephaloceles, and possible brain abscess, or meningitis. The loss of

anatomic continuity from the anterior or middle cranial fossa with the orbit, sphenoid sinus, or nasopharynx is a common pattern seen in sub-acute or delayed CSF leaks. Many of these leaks are sub-acute or delayed and noticed only after the period of acute cerebral edema. Once the brain has relaxed and retracted from the underlying skull base defect the disrupted dural can no longer contain the CSF [22, 23]. This becomes a two-way tract for microbes and CSF leakage. CSF can leak via the skin, the eustachian tube, sphenoid sinus, orbit, ethmoids, petrous bone, mastoid air cells, or even from the posterior fossa via the clivus. Identification of the CSF can be performed with a combination of CT-metrizimide, fluorescein, and nuclear medicine plegett studies [24]. Having a high likelihood of suspicion and early detection and intervention helps prevent life-threatening complications. A combination of skull base injury, hemicraniectomy, and CSF leakage can create a lethal triad leading to “paradoxical” herniation [25]. Those defects in the midline are best treated endoscopically while those more laterally placed are best treated with an open reconstructive ablative approach. The defects involving the frontal sinuses and orbital region require the use of bony reconstruction, soft-tissue reconstruction, multi-layer closure, and frontal sinus exenteration with obstruction of the nasofrontal duct. The concept of orbitofrontal reconstruction early allows a reference point of registration for future cranial reconstruction and maintenance of the facial proportions [26]. These steps are intimately related with early orbital-facial reconstruction tied to skull base reconstruction decreasing the risk for CSF leakage and both functional and aesthetic skeletal restoration.

DELAYED MANAGEMENT: TRAUMATIC VASOSPASM AND ANEURYSMS

Traumatic cerebral vasospasm, or a reduction in the caliber of cerebral arteries in response to some external stress, is a condition that has frequently complicated critical care management in patients with severe closed and penetrating head injury from the conflicts in Iraq and Afghanistan [4, 5]. Vasospasm, in general, can result in a reduction in blood flow to whatever organ is subserved by the effected artery. In the case of cerebral vasospasm, the clinical consequence can be delayed ischemic neurologic deficits and stroke. In a study of 119 military patients who suffered blast injury over a two-year period, many of whom required decompressive craniectomy at the time of initial management, 47% had concomitant cerebral vasospasm. The presence of vasospasm in this population was predicted by the extent of brain injury and the presence of traumatic aneurysms, and portended a worse early clinical outcome [4, 5]. Like vasospasm that follows subarachnoid hemorrhage, the vasospasm seen in the setting of blast induced head injury was reliably followed by transcranial Doppler ultrasonography, and was safely treated with balloon angioplasty [5].

In general, there should be a high index of suspicion for the presence of vasospasm and traumatic aneurysms in patients with blast induced closed and penetrating brain injury with or without decompressive craniectomy. Patients, especially those with penetrating injury, should receive a routine diagnostic cerebral angiogram during their early hospital stay and should be followed with daily transcranial Doppler ultrasonography. (FIGURE 1) Traumatic aneurysms should be treated at the time of diagnosis secondary to the risk of delayed rupture [4]. Treatment strategies in this setting can include open surgical resection, clipping, endovascular

coil occlusion, or a combination of both [2, 3]. Those with worsening vasospasm on TCD's and a poor baseline neurologic examination may benefit from multi-modal monitoring strategies that can help guide critical care management, including brain tissue oxygen monitoring and quantitative pupillometry. Critical care management strategies should at a baseline include maintenance of adequate mean arterial pressure, adequate circulating blood volume, normothermia, and maintenance of normal intracranial pressure. With respect to cerebral vasospasm, continued increase in mean flow velocities and worsening clinical status should prompt repeat cerebral angiogram and possible endovascular intervention (balloon angioplasty, spasmolytics) if indicated [5].

DELAYED MANAGEMENT: ENLARGING CRANIECTOMY

There are few circumstances that are more frustrating than the management of patients who have received inadequate craniectomy during their initial surgical management. While there may be many explanations for why this might occur, in almost every circumstance it relates to a lack of recognition or understanding of the extent of injury by the initial operating neurosurgeon. (FIGURE 2) With respect to the management of severe closed head injury, the Brain Trauma Foundation recently recommended that the size of a frontotemporoparietal decompressive craniectomy be "not less than 12 x 15 cm or 15 cm in diameter"[7]. Evidence that the decompression is too small may include fungating herniation of both normal and injured brain through the decompression. Should a diagnosis of inadequate decompressive craniectomy be made during the course of critical care management, every effort should be made to enlarge the craniectomy if there is persistent elevation in intracranial pressure or fungating brain from the cranial defect. Alternatively, bilateral or bi-compartmental craniectomy has been reported. In 2011, Ecker et al. reported on 33 patients from OIF/OEF undergoing such procedures. While 7 (23%) had died from their injury, 18 (60%) had a Glasgow Outcome Score (GOS) of 4 or 5 [27]. While this is a very select population, it is an option to be considered (Figure 3).

DELAYED MANAGEMENT: THE EFFECT OF POLYTRAUMA ON PATIENTS WITH A DECOMPRESSIVE CRANIECTOMY

Initial management of the polytrauma patient is appropriately dictated by ATLS principles. The presence of concomitant severe brain injury requiring decompressive craniectomy and polytrauma can complicate follow on critical care management significantly. The possible management scenarios are numerous and beyond the scope of this chapter. Needless to say, polytrauma often requires balance so that all organ systems may function and heal. This may include permissive hypercapnia or prone positioning in the scenario of severe acute respiratory distress syndrome (ARDS) or elevated positive end expiratory pressure (PEEP) more so than is normally allowed. Conversely, other services may need to change positioning standards in the operating room to accommodate the need for head positioning, such as when working on an extremity. Polytrauma in a patient with a decompressive craniectomy requires frequent communication based on a multidisciplinary team approach.

For the neurosurgeon, it is imperative to understand the implications of other procedures and therapies on the injured brain.

There is one particular issue that remains controversial and for which there are limited data to guide practice- the appropriate timing and agent for chemical deep vein thrombosis prophylaxis in the setting of severe traumatic brain injury. It is well known that severe systemic trauma can increase the risk for the formation of deep vein thrombosis (DVT), that the presence of DVT's increases the risk of pulmonary embolism, and that pulmonary embolism can worsen outcomes in trauma by a full order of magnitude compared to those without [28, 29]. Additionally, there is a well-known and particular association between TBI and hypercoagulability [30-32]. In a study of 408 severe TBI patients from the first 5 years of OIF, there was a 7% incidence of pulmonary embolism [6]. Despite the known association, neurosurgeons in particular have been reluctant to treat with chemical prophylaxis secondary to the possible risk of delayed cerebral hemorrhage expansion. The reluctance to treat has in part resulted from a relative paucity of supporting clinical and basic science research [33-36]. There is so much ambiguity in this area that while the 4th Edition of the TBI guidelines supports a level 3 recommendation for the use of low molecular weight heparin or unfractionated heparin, there are insufficient data to recommend preferred agent, dose or timing of pharmacologic prophylaxis [7].

Still, because of the disturbingly high association between severe military TBI and venous thromboembolic events, a strategy of early chemoprophylaxis (24 hours from injury) was instituted. A study was recently conducted to assess the safety and efficacy of this practice in the most severely injured patients: those with penetrating brain injury [37]. A total of 65 patients with penetrating brain injury from OEF were evaluated over a three-year period. Roughly half the patients received chemical DVT prophylaxis within 24 hours of injury. The study revealed a venous thromboembolism rate of 15%. Overall, there was no increased risk of hemorrhagic expansion in those who received early chemical DVT prophylaxis, and there was a trend towards a reduction in DVT and PE. What remains clear is that further research in this area is clearly needed to guide care.

DELAYED MANAGEMENT: CRANIOPLASTY

Cranioplasty is often considered the more straightforward aspect of the care for a patient with a decompressive craniectomy. As noted throughout this chapter, the care for service members that require a decompressive craniectomy secondary to military munitions are far from straightforward. Traditional military munitions tend to involve higher velocity rounds, resulting in greater dissipation of kinetic energy to the surrounding brain in penetrating head injury. Additionally, blast related trauma involves multiple mechanisms of injury not often seen in civilian settings [38].

In 2010, Stephens et al. detailed complications related to cranioplasty in 108 military service members injured during OIF/OEF, finding an overall complication rate of 24% with one death [39]. Twelve patients (11%) required prosthesis removal for extra-axial hematoma or infection. Timing of cranioplasty is balanced between infectious issues, the presence of other polytrauma injuries, and the stage of recovery/rehabilitation. To help avoid implant failure, patients with a transfrontal, transorbital, or transfascial trajectory of their initial injury

need to have their frontal-orbital bar evaluated and reconstructed prior to cranioplasty if there is an anticipated two centimeter or greater gap from the dura to the cranial reconstruction [26, 40]. Given the polytrauma nature of many of these patients, it is recommended that the calvarial bone is discarded at the time of the decompressive and therefore, not available for reconstruction [8].

CONCLUSION

The management of a severe traumatic brain injury who has undergone a decompressive craniectomy in a theater of war does not stop after the initial surgery. The collective experience from OIF and OEF has taught us valuable lessons in the follow on care and complication management of these patients. Many of these issues require vigilance and an index of suspicion, allowing early treatment. While outcome data is relatively limited, decompressive craniectomy allows for the safe transport of head injured patients out of theater and to advanced levels of care.

ABSTRACT

Cerebral edema and intracranial hypertension can occur through impaired autoregulation following traumatic brain injury (TBI). The role of decompressive craniectomy (DC) in severe TBI remains controversial owing to conflicting data, particularly from randomized controlled trials. Some argue that DC may simply increase the number of patients who survive but remain in a vegetative state. There are also differences in opinion regarding optimal surgical technique. This chapter summarizes the published evidenced-based guidelines on the utilization of DC for the treatment of severe TBI.

Keywords: guidelines, traumatic brain injury, outcome, decompressive craniectomy

INTRODUCTION

Preventing cerebral hypoxia and hypotension and resultant secondary injury is the main goal of treatment following severe traumatic brain injury (TBI). Cerebral edema can occur through impaired autoregulation after injury leading to disruption of the normal homeostatic mechanisms [1] and resulting in a vicious cycle of increased intracranial hypertension, reduced cerebral blood flow, and metabolic dysfunction [2, 3]. As pressure within the skull increases, brain tissue displacement can lead to cerebral herniation, culminating in significant morbidity or mortality [4-6].

Decompressive craniectomy (DC), the surgical removal of a portion of the cranium, has been performed for many years in patients with TBI [7]. In patients with elevated intracranial pressure (ICP), DC has been reported to improve cerebral perfusion and oxygenation, with outcome improvement in posttraumatic patients with intractable intracranial hypertension [8, 9]. Primary DC is accomplished when the bone flap is not replaced after evacuation of an intracranial hematoma in the early phases of TBI, whereas secondary DC is employed when the cranium is removed after failure to control intracranial hypertension by other methods [10, 11].

The pivotal issue of managing ICP increases in TBI patients is comparable to what is seen in compartment syndromes. For example, in abdominal compartment syndrome, as intra-abdominal pressure rises, splanchnic blood flow declines. Subsequently, this can potentiate a sequelae of progressively adverse effects on cardiac, pulmonary, and renal systems. When intra-abdominal pressure reaches critical levels, abdominal fascial release through open laparotomy is the standard of care [12].

The controversy surrounding the role of DC in severe TBI results from conflicting data, particularly from randomized controlled trials (RCTs), assessing both primary and secondary DC [10, 13-15]. Controversy still exists on whether DC may simply increase the number of patients who survive but remain in a vegetative state [11, 15]. Additionally, opinion varies widely regarding the specific surgical technique utilized in patients undergoing DC. Over the past three decades, numerous clinical trials and observational studies have tried to address these variations including investigating craniectomy dimensions, craniectomy versus craniotomy, and timing of surgery [16-20]. In general, most of the evidence surrounding DC in trauma is based on low-quality RCTs, moderate- to low-quality cohort or case control studies, case series, and other non-comparative designs. Consequently owing to inconsistent clinical data, the level of confidence for treatment efficacy has been reduced.

METHODS

The Brain Trauma Foundation's Guidelines for the Management of Severe Traumatic Brain Injury, 4th edition, most recently updated in January 2017 [21], developed evidence-based recommendations based on research studies categorized as Class 1, 2, or 3 that constituted high, moderate, or low confidence, respectively. The class assignments were made on the basis of the extent to which the evidence reflected the true effect based on a combination of study design and how the risk of bias was addressed. Specifically, Class 1, the highest assignment, is limited to good-quality randomized trials. Class 2 includes moderate-

quality randomized controlled trials and good-quality cohort or case-control studies. Class 3, the lowest assignment, is given to low-quality randomized controlled trials, moderate- to low-quality cohort or case control studies, and case series and other non-comparative designs [21]. Levels of recommendations were based on the strength of the body of evidence, and recommendations were divided into Level I (low risk of bias RCTs), Level IIA and II B, and Level III recommendations, which constituted high-, moderate-, and low-quality evidence, respectively [21].

The 4th edition included the results from the Decompressive Craniectomy Trial (DECRA) in diffuse TBI (22), but it went to press shortly before the initial advanced publication of the largest multinational RCT, the Randomized Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure (RESCUEicp) trial, which pragmatically evaluated the role of DC in the management of refractory cerebral hypertension [15]. The current guidelines analyzed 31 potentially relevant studies and excluded 21 studies not meeting inclusion criteria. The ten remaining studies included one Class 1 study [22], two Class 2 studies [23, 24], and seven Class 3 studies [16-20, 25, 26].

Class 1 Study: DC versus Initial Medical Management

The DECRA trial is an RCT that compared bifrontotemporoparietal DC to initial medical management for refractory intracranial hypertension, with refractory ICP defined as >20 mm Hg for 15 minutes within a 1-hour period. The investigators recruited patients in fifteen tertiary care hospitals in three countries between 2002 and 2010 [22]. The Brain Trauma Foundation characterized this study's evidence as Class 1. The DC group included 73 patients and the medical management group included 82. The study found worse Extended Glasgow Outcome Scale (GOS-E) scores for patients in the DC group than those in standard care at 6 months post-injury although DC patients had lower ICP and fewer ICU days. Mortality at 6 months was 19% in the DC group versus 18% in the medical management groups (not statistically significant). Interestingly, the proportion of patients in the DC group with reactivity in neither pupil on admission was higher (27% versus 12%, $P = 0.04$) than in controls. Adjustment for pupil reactivity after post hoc analysis revealed the between-group differences were no longer significant for the score on the GOS-E (adjusted odds ratio, 1.53; 95% confidence interval [CI]: 0.86 to 2.73; $P = 0.15$) or for the risk of an unfavorable outcome (adjusted odds ratio, 1.90; 95% CI: 0.95 to 3.79; $P = 0.07$), although a suggestion of harm remained. The Guidelines Panel concluded that, although the study was of high quality, it was ultimately a single study, and replication was needed for higher confidence in the results [21].

Class 2 Study: Size of DC

The Guidelines classified two studies as Class 2 that evaluated the role of differently sized craniectomy bone flaps and their effect on patient mortality and functional outcomes. These studies did not include a non-decompressed comparison group. The quality of the body of evidence was deemed to be moderate.

Jiang et al. [23] conducted a multi-institutional RCT comparing the influence of unilateral frontoparietal (12 x 15 cm) versus a smaller temporoparietal (6 x 8 cm) DC on patient outcomes. This study was conducted at five medical centers in China. Inclusion criteria consisted of patients with refractory intracranial hypertension. The larger-sized craniectomy group included 245 patients and the smaller-sized craniectomy group included 241 patients. Larger craniectomies were associated with better GOS-E scores than smaller craniectomies, with GOS-E scores of 4 or 5 (39.8% versus 28.6%), GOS-E scores of 2 or 3 (34% versus 36.3%), and GOS-E scores of 1 (26.2% versus 35.1%), respectively [23].

Qiu et al. (24) conducted a RCT comparing the influence of unilateral 15-cm craniectomy versus routine temporoparietal craniectomy on patient outcomes. This study was conducted at only a single site. The inclusion criteria necessitated computed tomography (CT) evidence showing intracranial swelling. The larger DC group included 37 patients and the routine DC group also included 37 patients. GOS-E scores of 4 or 5 for the larger DC group versus the smaller DC group at 1 year were 56.8% versus 32.4%, and mortality was 27% versus 57% ($P = 0.010$), respectively. There was also evidence of increased rates of complications for the larger DC group [24]. In both Class 2 studies, the Guidelines' authors expressed concern regarding baseline differences in patients, procedures, and treatment and the lack of adjustment for any covariates in both studies.

Class 3 Study

Class 3 studies were not integrated into the recommendations. The body of evidence was rated as insufficient, primarily because the results were inconsistent, and it was not feasible to resolve these differing results given the quality of the studies. Following is a summary of the seven Class 3 studies.

DC versus Medical Management

Olivecrona et al. utilized a retrospective cohort study comparing DC ($N = 21$) with medical management ($N = 72$). The results did not show any significant differences in mortality: 14.4% versus 14.1% in the DC and medical management groups, respectively; GOS-E score 5-4 was 71% versus 61%; GOS-E score 3 was 9.6% versus 21.1%; and GOS-E score 2 was 4.8% versus 4.2%. Of note, the reduction of ICP was statistically significant in the DC group 72 hours post-procedure [25].

Soustiel et al. conducted a prospective cohort study comparing DC ($N = 36$) with medical management ($N = 86$). Mortality and GOS-E score were adjusted for age, CT scan, Glasgow Coma Score (GCS) at admission, ICP, cerebral blood flow, and cerebral metabolic rate of oxygen. The results did not show any significant differences in mortality (odds ratio 0.8, $P = 0.4185$), but there was significantly improved functional outcome at 6 months (odds ratio 0.14, $P \leq 0.05$) [26].

DC versus Craniotomy

Huang et al. compared DC with duraplasty ($N = 38$) to craniotomy ($N = 16$) in a retrospective cohort study of the treatment of hemorrhagic cerebral contusion. Their results showed no significant differences in mortality (13.2% versus 25%) but lower re-operative

rates (7.9% versus 37.5%) and better GOS-E scores (5.55 versus 3.25) in the DC group versus the craniotomy group [16].

Soukiasian et al. compared DC (N = 24) to craniotomy (N = 96) in a retrospective cohort study that evaluated mortality, TBI, and complications. The results again showed no difference in mortality and no difference in survival between groups, 52% versus 79%, in DC versus craniotomy. Complications included collapse of basilar cisterns (30.4% versus 4.3%) and herniation (17.4% versus 5.4%) in DC versus craniotomy [17].

Large versus Small DC

Lu et al. compared large (N = 115) versus small (N = 115) DC in an observational study and measured mortality, GOS-E scores, and complications. In their comparison, there was a significant difference in mortality (41.7% versus 57.7%), but no difference in GOS-E scores for good outcomes (25% versus 18.3%) or GOS-E scores for severe disability/vegetative survival (34.8% versus 24.3%). This Class 3 study's conclusions are similar to those of a higher quality Class 2 study [20].

Earlier versus Later DC

Akyuz et al. compared DC as a second-tier (N = 36) versus first-tier (N = 40) treatment for severe TBI in an observational study and evaluated mortality, GOS-E scores, ICP, and complications. First-tier or early DC was performed for patients with an opening ICP above 25 mm Hg. There was a significant difference in mortality, 44.4% versus 12.5% (P = 0.0018), but no difference in GOS-E scores 4 and 5, 27.8% versus 50% (P = 0.047), in second-tier versus first-tier treatments. This Class 3 study suggested that early DC resulted in better outcomes [18]. Wen et al. compared early DC (N = 25) versus late DC (N = 19) in a prospective cohort and evaluated mortality, GOS-E scores, and complications. This study found no difference in outcomes between the groups in terms of mortality or GOS-E scores [19].

APPLICABILITY OF STUDIES

The assessment of applicability differed across the studies and topics. Of note, the one Class 1 RCT was conducted over an 8-year period and was multinational [22]. Although the variety in patient selection may have limited the ability to detect an effect, it could increase the applicability of the study. The applicability of the two Class 2 RCTs comparing large versus small DC may be limited as they were both conducted in a single country (China), which may differ in important ways that could not be controlled for in the analysis [23, 24].

SUMMARY OF THE RECOMMENDATIONS REGARDING DC FROM THE 4TH EDITION

There were insufficient data to support a Level I (highest level representing high quality, strong evidence) recommendation for utilizing DC for the management of intracranial hypertension secondary to severe TBI (21). One Level IIA recommendation is that “bifrontal

DC is not recommended to improve outcomes as measured by GOS-E scores at 6 months post-injury in severe TBI patients with diffuse injury (without mass lesions) and with ICP elevations to values >20 mm Hg for more than 15 minutes within a 1-hour period that are refractory to first-tier therapies. However, it [DC] was demonstrated to reduce ICP and to minimize days in the intensive care unit” [22]. Another Level IIA recommendation is that “large frontotemporoparietal DC (not less than 12 x 15 cm or 15 cm in diameter) is recommended over a small frontotemporoparietal DC for reduced mortality and improved neurologic outcomes in patients with severe TBI” [23, 24].

PREVIOUS PUBLISHED GUIDELINES

DC was initially addressed in three articles among several published in 2006 as the Guidelines for the Surgical Management of Traumatic Brain Injury. For acute subdural hematomas, the recommended method for surgical evacuation was craniotomy with or without bone flap removal and duraplasty [27]. In regard to traumatic parenchymal lesions for patients with diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension, a bifrontal DC within 48 hours was recommended. Moreover, for patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation, utilization of decompressive procedures, including subtemporal decompression, temporal lobectomy, and hemispheric decompressive craniectomy, were advocated [28]. Additionally, suboccipital craniectomy was recommended for significant traumatic posterior fossa mass lesions [29].

The second edition of The Guidelines for the Acute Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents, published in 2012 [30], featured a new chapter on DC for the treatment of intracranial hypertension. The lowest of three levels of recommendation, based on the quality of evidence, is as follows: “DC with duraplasty, leaving the bone flap out, may be considered for pediatric patients with TBI who are showing early signs of neurologic deterioration or herniation or are developing intracranial hypertension refractory to medical management during the early stages of their treatment” [30]. Furthermore, the included studies were mostly retrospective case series, with the exception of one study that used a prospectively collected database [31]. There were no internal or matched external controls, and no RCTs were included. Notably, a RCT conducted by Taylor et al. in 2001 on early DC in children with TBI and sustained intracranial hypertension was excluded from the guidelines because of prolonged patient accrual time, utilization of an unusual bilateral mid-temporal craniectomy technique, and the inclusion of patients with a GCS >8 [32]. The authors of the Guidelines concluded that it was impossible to accurately compare the cohorts between these various studies given the scarcity of descriptive statistics [30].

NEW EVIDENCE

The RESCUEicp trial is an RCT that aimed to evaluate the effectiveness of DC offered as late-tier treatment for patients with TBI and refractory intracranial hypertension (>25 mm

Hg). This pragmatic study randomized 402 patients, aged 10 to 65 years, in 52 centers and twenty countries between 2004 and 2014. The DC group included 206 patients, and the medical management group included 196 patients. Patients had to be between 10 and 65 years of age, have a TBI with an abnormal computed tomographic scan of the brain, have an ICP monitor in place, and have refractory ICP (>25 mm Hg for 1 to 12 hours) despite maximum treatment measures (with the exclusion of barbiturate utilization). Patients who had undergone an immediate operation for evacuation of an intracranial hematoma could be included as long as the operation was not a craniectomy. Patients were excluded if they had bilateral fixed and dilated pupils, bleeding diathesis, or an injury that was deemed to be incompatible with life [15].

The GOS-E scores at 6 months were: death, 26.9% among patients in the surgical group versus 48.9% among patients in the medical group; vegetative state, 8.5% versus 2.1%; lower severe disability (reliant on others for care), 21.9% versus 14.4%; upper severe disability (autonomous at home), 15.4% versus 8.0%; moderate disability, 23.4% versus 19.7%; and good recovery, 4.0% versus 6.9%. The GOS-E scores at 12 months were: death, 30.4% versus 52.0%; vegetative state, 6.2% versus 1.7%; lower severe disability, 18.0% versus 14.0%; upper severe disability, 13.4% versus 3.9%; moderate disability, 22.2% versus 20.1%; and good recovery, 9.8% versus 8.4%. Surgical patients had a higher rate of adverse events (16.3% versus 9.2%, $P = 0.03$) but fewer hours than medical patients with ICP above 25 mm Hg (median, 5.0 versus 17.0 hours; $P < 0.001$) [15].

The study concluded that, at 6 months, “decompressive craniectomy in patients with TBI and refractory intracranial hypertension resulted in lower mortality and higher rates of vegetative state, lower severe disability, and upper severe disability than medical care.” The two groups did not differ in regard to the rates of moderate disability or good recovery [15].

CONCLUSION

Despite the completion of the two largest RCTs comparing the efficacy of DC versus medical management for patients with TBI, the protocol for the management of refractory hypertension remains highly controversial. The DECRA study showed no advantage from early bifrontal surgical DC to reduce ICP in diffuse TBI, although the reliability of the results was arguable owing to the restrictive inclusion criteria. The RESCUEicp trial brought a new perspective to these issues by including more frequently encountered patient conditions and by refining the description of refractory intracranial hypertension (>25 mm Hg for 1 to 12 hours). The RESCUEicp trial showed that DC in patients who failed initial treatment measures was associated with lower mortality than in patients who underwent medical management. However, more survivors in the surgical group than those in the medical group were in a vegetative state or reliant on others for activities of daily living.

While these results may underscore the age-old belief that improvements in mortality from emergent lifesaving procedures do not necessarily correlate with enhancements in quality of life, there is concern for relying on 6-month outcome measures to define the treatment’s effectiveness for a condition (severe TBI) that demonstrates ongoing recovery for 12 to 24 months, or longer. Careful evaluation of the 12-month outcome for RESCUEicp suggests improvement in the DC cohort given that the upper severe disability group, by

definition, had partial independence at home. Twenty-four month follow-up is expected to be published after the data are analyzed. However, the conclusions thus far argue for greater scrutiny in selecting patients for DC and for improvement in our diagnosis and treatment through further research and technological innovation. For patients who sustain severe TBI, it is necessary to have early, comprehensive discussions with families regarding the risks/benefits of treatment and the potential prognosis for recovery.

ABSTRACT

There continues to be a debate regarding the role of decompressive craniectomy in the management of neurological crises. There is now clear evidence from recent randomized controlled trials that surgical decompression reduces mortality. However, in most of the trials this reduction in mortality was almost directly translatable into an increase in the number of survivors with either severe disability or in a vegetative state. The implications that these findings have for the ongoing use of the procedure in high income countries are significant given the socioeconomic implications of converting death into survival with complete dependency. However, there are limitations when applying the results of these trials to patients who require surgical intervention in low and middle income countries. There are significant and evolving differences in terms of global epidemiological disease patterns, prehospital care, in-hospital diagnostic facilities and rehabilitation facilities. The implications of performing “life-saving” surgery differ depending on the resources available and the application of outcome data from well-funded trials and the impact that use of such surgical techniques has on health care resources will vary markedly.

INTRODUCTION

The role of decompressive craniectomy (DC) in the management of neurological crises is the subject of considerable debate. Evidence from randomized controlled trials (RCTs) in the context of ischemic stroke [1-3] and severe traumatic brain injury (TBI) [4, 5] has been added to numerous retrospective studies reporting use of the procedure in other conditions such as subarachnoid hemorrhage [6, 7], infection [8, 9], venous sinus thrombosis [10, 11], and in certain inflammatory conditions [12, 13]. DC can be performed as either a primary or secondary procedure. A primary procedure is performed when the brain is determined to be swollen following evacuation of a mass lesion such as an acute subdural hematoma in the context of severe TBI or following removal of a lesion such as a tumor or abscess. A secondary procedure is performed for refractory intracranial hypertension despite maximal medical therapy. This can be in the context of intracranial pressure (ICP) monitoring following severe TBI or following clinical deterioration in the context of ischemic stroke or infection [14].

A growing body of evidence has provided support for the use of DC as a life-saving intervention and recent RCTs demonstrated that a significant reduction in mortality can be achieved [1-5]. However, evidence that surgical intervention improves clinical outcome has been less forthcoming. Indeed, evidence from these trials has demonstrated that the reduction in mortality led to an almost direct increase in the number of survivors with severe disability [15, 16].

The socioeconomic implications of this outcome will not be insignificant given the health care requirements of these survivors, especially for those patients in lower and middle income countries (LMICs) where resources can be limited. Further limitations must also be acknowledged when applying evidence obtained from trials conducted in high income countries (HICs) to LMICs because of the disproportionately high incidence of pathologies such as stroke and trauma in LMICs and the fewer available health care resources. This shortfall in resources applies to all aspects of surgical intervention ranging from prehospital care, in-hospital diagnostic facilities, monitoring, and therapeutic resources, through to rehabilitation and nursing home facilities.

The aim of this chapter is to examine the impact that the mismatch between the epidemiology of pathology and the availability of resources can have on the management of patients who may require DC.

DECOMPRESSIVE CRANIECTOMY – EVOLVING EPIDEMIOLOGY

The global epidemiological patterns for many of the conditions that require consideration for DC have changed considerably over recent years. In the context of severe TBI, motor vehicle accidents have always contributed significantly to the global burden of disease. However, in HICs the number of total TBI events has been decreasing, and the main cause of

severe TBI is now falls in elderly patients [17, 18]. Probably, no single reason accounts for this change, and several interrelated factors may be responsible, for example, improvements in car design, the introduction of air bags, preventative legislation such as the compulsory wearing of seat belts and motor cycle helmets, the need to adhere to strict speed limits, and drink drive laws. Improved control of cardiovascular disease has led to a longer life expectancy with the attendant increase in risk for falls among the elderly.

In LMICs, while the use of motor vehicles and motor cycles has increased, it has not been accompanied by improvement in laws to prevent unsafe driving habits. Similarly, traffic safety education remains lacking in this setting. Given these problems it is probably unsurprising that although only 54% of the world's registered vehicles are in LMICs, 90% of the deaths attributable to road traffic accidents occur in LMICs. Furthermore, because of limited reporting systems (i.e., trauma registries) in LMICs, this is likely to be an underestimation [18, 19]. Finally, the type of head injuries may differ between patients considered for DC in HICs and LMICs because most patients with TBI in LMICs are pedestrians, cyclists, and motorcyclists who often have no helmet protection. In addition, in certain regions where the prevalence of armed violence is high (Central America, the Middle East, and Central Africa), assault and gunshot injuries are important causes of TBI, which may further contribute to the difference in injury patterns in patients who present for treatment [18].

In the context of ischemic stroke, there are similar differences between the types of patients who are considered for DC in HICs and LMICs. In HICs age standardized stroke mortality and morbidity rates have steadily decreased over recent years with subsequent declines in absolute stroke mortality and morbidity [20]. A good example of this reduction can be seen in data from the United States where, for many years, stroke was the third most common cause of death. In 2008, however, it dropped to fourth place and 5 years later to fifth place [21]. Other HICs have similar findings, and mortality rates are likely to improve further with the introduction of endovascular techniques using either intra-arterial therapy or mechanical thrombectomy [22-24]. Findings in LMICs, however, show that stroke remains the third most common cause of death and disability. Many factors contribute to this, not the least of which are the worldwide prevalence of hypertension and an increase in other risk factors such as high fasting blood glucose, high total cholesterol, and tobacco smoking, all of which have historically been more prevalent in HICs [25].

The data are less robust on the epidemiology of other conditions for which patients present and are subsequently considered for DC. Even so, it must be acknowledged that the manner in which patients present and their disease severity may vary between HICs and LMICs. These differences may be further compounded by the health care resources available for prehospital, in-hospital, and rehabilitative care.

DECOMPRESSIVE CRANIECTOMY – PREHOSPITAL CARE

The aims of prehospital care for patients who may require DC are early diagnosis and resuscitation, avoidance of secondary insults such as hypoxia and hypotension, and rapid transport of patients to an appropriate health care facility. In the context of trauma, most HICs have well-organized trauma systems with highly trained paramedical staff, critical to the

management of TBI patients [26]. Prehospital management is directed toward preventing secondary brain injury while facilitating rapid transport to a facility that can provide neurocritical care. Initial management includes the assessment of respiratory and cardiovascular systems, consciousness level, and examination of the pupillary reactivity. In many HICs, the increasing use of prehospital intubation and ventilation has benefited survival when applied efficaciously [27, 28].

In the context of ischemic stroke, the need for a rapid diagnosis, resuscitation, and transport has increased following the development and subsequent proven efficacy of endovascular techniques such as intra-arterial therapy or mechanical thrombectomy [21-23]. This has also led to the development of well-integrated stroke response teams aimed at reducing the so-called “door to needle” time in order to initiate these time-critical endovascular therapies.

In LMICs, available prehospital resources vary greatly. Nielsen et al. performed a survey to determine the status of prehospital care in a wide range of LMICs [29]. They found that a substantial number of critically ill patients are transported by commercial and private vehicles with very limited life support capabilities. Similarly, Smart et al. reported that in Mwanza, the second most populated area in Tanzania, the majority of patients are transported to hospital in private vehicles including taxis [30].

Obviously, in these circumstances the drivers and prehospital care providers will have very limited, if any, paramedical training, and it is therefore remarkable that hypotension and hypoxia on hospital arrival did not seem to be associated with poor outcome [29]. Although this finding seems counterintuitive, it serves to emphasize the self-selecting aspect of limited prehospital care. It is highly likely that given the often-long distances involved, those patients in LMICs with either a very severe TBI or stroke will not survive the journey to hospital, and those who do survive may have a different injury pattern and severity than patients who present in HICs. This again serves to emphasize the inherent difficulties in comparing data from different health care regions.

DECOMPRESSIVE CRANIECTOMY – NEUROCRITICAL CARE

Over recent years the medical management of patients in the intensive neurocritical care setting in HICs has become increasingly specialized. Management is targeted at optimizing cerebral perfusion and oxygenation with a view to minimizing secondary insults. A number of studies have demonstrated that specialist protocol-driven management can improve long-term clinical outcome, especially in the context of severe TBI [31-33]. Sedation and ventilation allow full control of cerebral perfusion and oxygenation, prevent agitation due to pain and distress, and facilitate ICP monitoring in order to identify those patients who develop either surgical lesions requiring evacuation or progressive cerebral swelling that would preclude early weaning [34-37]. This ICP-targeted approach aims to maintain the pressure below a certain threshold via interventions introduced in a stepwise protocol-driven manner [38]. These include head elevation, further sedation and paralysis, cerebrospinal fluid (CSF) drainage, osmotherapy, barbiturate therapy, and more recently, hypothermia and surgical decompression. Rapid access to neuroimaging is critical in this regard since it can differentiate between those patients who develop a mass lesion that requires evacuation and

those patients who develop diffuse swelling and may therefore be a candidate for surgical decompression.

In addition to these therapeutic options, multimodal monitoring techniques have been developed so that it is now possible to obtain continuous data on a number of physiological and biochemical parameters [36]. The aim of these monitors is to gather as much information as possible in order to limit the progression of the primary brain injury and accurately assess the development and severity of secondary injuries so that appropriate treatment can be instigated. Considerable debate, however, continues about the benefit provided by data that may merely reflect the severity of the injury rather than provide information that may guide therapy. Indeed, it has even been suggested that invasive monitoring merely increases the number of medical and surgical interventions and may actually worsen outcome [39, 40]. However, adopting this position fails to recognize that it is not the monitoring that harms the patient but is instead the clinicians' interpretation of the information gained and the appropriateness of the clinical response [41].

In LMICs, the extent to which neurocritical resources are available varies widely [42 - 45]. Often, there are few or no intensive care facilities and only limited access to mechanical ventilation or neurocritical monitoring [44]. Such restrictive conditions can lead to innovative practices, as described by Gupta et al. who recently published a study describing the use of resterilized intraparenchymal strain gauge catheters. Sixty-six consecutive patients with severe TBI were monitored using catheters that had been resterilized with ethylene oxide. No increase in meningitis was observed. These catheters, after sterilization, could be reused two to four times and reliably recorded the ICP with insignificant drift [45].

Such significant differences in neurocritical care settings in HICs and LMICs must be taken into account when considering patient selection for surgical decompression.

PATIENT SELECTION

In HICs with advanced neurocritical care and monitoring facilities, the use of ICP monitoring in severe TBI has become routine and plays an important role in patient selection for surgical decompression [34 -36]. In general, an ICP of 20 mm Hg has been used as the threshold at which to instigate medical therapies aimed at maintaining cerebral perfusion. This practice is based on the observation of a strong correlation between outcome and the number of hours the ICP remains above 20 mm Hg [47, 48]. It has also been demonstrated that patients whose ICP can be satisfactorily controlled below this level have a better outcome than those with intractably raised ICP [49, 50]. Still, debate continues about the precise threshold ICP at which surgical intervention should be initiated because it is becoming increasingly apparent that the reduction in ICP achieved by surgical decompression is not necessarily converted into an improvement in outcome. This was clearly demonstrated by the Decompressive Craniectomy (DECRA) study in which patients randomized to the surgical arm of the trial had significantly lower ICPs and spent less time in intensive care. However, at 6 months follow-up their outcomes were worse than those of patients randomized to medical therapy [4].

These findings serve to highlight not only the morbidity of the procedure but also the limitations of interpreting outcome data from LMICs where patient selection is less specific.

Adeleye reported a good example of this practice in a Nigerian neurosurgical unit, where the only monitoring available was the clinical examination. Based on the observation that young patients with mild or moderate head injury often die suddenly a few days after admission from what appears to be an intracranial event following evacuation of hematoma, Adeleye performed DC not only for severe TBI but also for mild and moderate TBI in order to “prevent” clinical deterioration [51]. This type of practice can be justified if there is limited access to postoperative imaging following a primary decompressive procedure; however, it again serves to emphasize the inherent difficulties in comparing outcome studies in HICs versus LMICs.

Similar difficulties arise with other neurological pathologies such as stroke and subarachnoid hemorrhage. Given the limitations of using the ICP as a marker of injury severity, determination of severity relies largely on radiological findings, which are readily available in HICs but obviously far less so in LMICs, which will again skew any comparison of outcomes.

SURGICAL TECHNIQUE

In HICs with well-organized neurosurgical services, the technical requirements of the surgical procedure are relatively straightforward. A large scalp flap is reflected, which usually covers as wide an area as possible within the confines of patient positioning. A large bone flap, either bifrontal or unilateral, is removed, the dura is opened, and a duraplasty is often performed with a dural substitute. Depending on institutional practices, the bone flap is either discarded or stored in a refrigerator. Once the patient has recovered from the neurological crisis that necessitated the decompressive procedure, a cranioplasty procedure is performed with either the autologous bone or a suitable substitute material.

Until recently, both the decompressive procedure and cranioplasty were perceived to be relatively straightforward; however, it is becoming increasingly apparent that both procedures are associated with significant morbidity [52]. The impact that this has in HICs the economic impact of increased morbidity is likely to be relatively small in the context of the overall health care budget, but in LMICs where economic resources are limited, these costs present a major health care problem [44].

Another problem that needs special consideration in LMICs is the reconstructive cranioplasty, which requires that the autologous bone flap be stored for a period of time in a designated refrigerator at a specific temperature. Such storage presents not only financial difficulties but also logistical problems related to long-term follow-up. Several solutions to this problem have been suggested. One of the most common solutions is to store the bone flap in the anterior abdomen. Although some suggest that this method of preservation is associated with an increased complication rate, a recent meta-analysis found no difference in complications between subcutaneous abdominal implantation and cryopreserved bone flaps [53]. Notwithstanding these findings, it is still necessary that the patient be appropriately followed up, which does present logistical problems in many LMICs.

Other technical modifications of decompressive surgery have been suggested. One modification is that the floating bone flap after craniotomy is not removed but rather left to either freely float over the skull defect or be held loosely in place with sutures. Mezue et al.

report this technique and emphasize the need for a large bone flap to be reflected [54]. They report a mortality of 21%, which is consistent with DC results in HICs. It is yet to be determined whether this procedure always provides adequate decompression; however, the avoidance of the need for a second surgical procedure makes economic sense.

Adeleye describes a hinge decompressive craniectomy (hDC) in which the frontotemporoparietal skull flap is hinged on the temporal muscle [42]. The advantage of this technique is that it too eliminates the need for the subsequent cranioplasty, and the authors report 40 consecutive cases without apparent complications. Peethambaran et al. describe a four-quadrant osteoplastic DC that avoids cranioplasty [55, 56]. These authors of both studies emphasize that the main advantage of these procedures is avoidance of the need for a second procedure to replace the bone flap. However, it should be noted that in both studies the mortality rate was extremely high. This may of course be a reflection of injury severity however, caution must always be exercised when a new procedure appears to be associated with a very poor outcome (Table 2).

A final surgical technique that requires consideration is that of cisternotomy. In this procedure the basal cisterns are systematically opened in order to drain CSF and reduce the ICP [57, 58]. Although the authors describe the backflow of the CSF that can be achieved through the Virchow-Robin spaces with subsequent decrease in ICP, the clinical evidence supporting these assertions is limited.

OUTCOME

Despite the problems associated with the selection of patients for decompressive craniectomy in LMICs, an even greater challenge faces those patients who survive the surgery. Highly problematic in LMICs are both long-term outcome and the resources available to care for those who survive with severe disability.

These difficulties are compounded by the lack of outcome studies for patients in LMICs. Published reports have documented only outcome at discharge (Table 1). Comparing these limited data with fuller outcome data from HICs is problematic and for this reason, any application of the results from the recent RCTs to clinical practice in LMICs requires caution.

The pooled analysis of the three European stroke studies clearly demonstrated a significant reduction in mortality from 71% in those patients randomized to standard medical therapy to 22% in those patients randomized to surgery [59]. However, this reduction in mortality was achieved primarily because of an increase in the number of patients who survived with a modified Rankin score of 4 (2% in those patients randomized to the standard medical therapy versus 31% in those patients randomized to surgical decompression). In the Decompressive Surgery for the Treatment of malignant infarction of the middle cerebral artery II (DESTINY II) study that investigated hemicraniectomy in patients over 60 years of age, the conversion of death into survival with dependency was even more striking [60]. Mortality was reduced from 70% to 33%, but among the twenty-seven patients who were randomized to surgery and survived, most were fully dependent with severe aphasia or neuropsychological deficits [61].

Table 1. Mortality and Good Outcome (GOSE 4-5) in main consecutive series of patients underwent DC for TBI reported in last five years. In the LMI countries the follow-up is mostly reported at discharge

Country	World Bank Country Classification	Author	Mortality	Good Outcome (GOS 4-5)

Legend: LMI: Lower middle income, UMI: Upper middle income, HI: High income, IH: In-Hospital, D: Discharge, FU: Follow-Up, m: months; NA : Not Available

Findings related to severe TBI have been similar. The DECRA study demonstrated that early surgical intervention provided no improvement in outcome, highlighting that surgical intervention is not without morbidity [4]. While the trial prompted some criticism, its findings certainly support caution when considering the approach by Adeleye because operating early will not necessarily improve outcome [51]. More recently, the Randomised Evaluation of Surgery with Elevation of Intracranial Pressure (RESCUEicp) trial confirmed a survival benefit, but again this came about only as a result of an increased number of dependent survivors [5, 62].

It is difficult to determine the impact that these findings should have on clinical practice in LMICs as only patients in HICs were studied and any therapeutic implications arising from these results should be applied with caution. Still, a number of issues are noteworthy. First, the trials have clearly established that surgical intervention does not reverse the effects of the pathology that precipitated the neurological crisis. Second, while surgical decompression reduces mortality, this procedure leads to an almost direct conversion into survival with severe disability and dependency. In HICs the financial manpower impact that this increase in the number of severely disabled survivors has on health care resources is significant but probably sustainable by most healthcare institutions, especially in the context of a well-funded RCT.

Table 2. Main consecutive series of patients underwent DC for TBI reported in last five years. The number of surgery and the mean age of patients is different related to the countries

Country	World Bank Country Classification	Author	Type of study	Number of center	Period of study	Number of DC/month (AVG)	Mean Age (y)
India	LMI	Bhat AR	Prospective	Single	Jun 2006 Jun 2011	3,7	NA

Cost effectiveness in itself should not be the overriding factor when considering the value of a therapeutic intervention, especially a definitive life-saving procedure. There is, nevertheless, a strong ethical imperative to consider the impact that any one particular procedure has on health care resources. Hofmeijer et al., recently reported the incremental costs per quality-adjusted life year gained after hemicraniectomy in young patients with malignant stroke [63]. They demonstrated that the costing represented approximately eleven times the gross domestic cost per capita for an LMIC such as Mexico [64]. Similar studies have been done in the context of severe TBI [65].

In most LMICs the health care resource implications of survival with severe disability are unknown, and this leads to the important issue of long-term outcome data collection. Given the limited funding available in LMICs, health care resources must be allocated appropriately. Proper collection of data on management and outcomes in LMICs is extremely important, and a prospective project funded by Western national or international agencies may help. Possibly, decompressive surgery provides benefit to patients in LMICs since they present in quite different circumstances from those of HICs. Alternatively, decompressive surgery in this setting may mainly convert death into survival with severe disability and dependency, thereby placing an unacceptable and unsustainable burden on scarce health care resources. The absence of robust databases allowing accurate statistical analysis impedes government efforts to adjust and apportion health care budgets appropriately.

CONCLUSION

Regarding the question “Do the indications for decompressive craniectomy change according to the available resources?”, the available data are probably insufficient for an objective assessment. What is certain is that the implications of performing “life-saving” surgery are very different for HICs and LHICs. Application of outcome data from well-funded RCTs in HICs to the patient populations in LMICs has major limitations given the different and evolving epidemiology and the surgical resources available in these two groups. In addition, the impact that use of such surgical techniques has on health care resources will vary markedly between HICs and LMICs.

If use of these procedures is to continue in LMICs, more active data collection is required in order to carry out robust cost-effectiveness analyses so that scarce resources can be applied appropriately and equitably.

ABSTRACT

Cranial defects requiring cranioplasty reconstruction can result from a variety of etiologies that require neurosurgical intervention for intracranial pathology. The goals of craniofacial reconstruction are to restore skull continuity for cerebral protection, restore craniofacial contour and symmetry, and reverse associated neurological deficits. Techniques and timing of cranioplasty reconstruction to optimize outcomes are presented and how to address accompanying bone flap defects is discussed.

Keywords: traumatic brain injury, decompressive craniectomy, cranioplasty

INTRODUCTION

Cranial defects requiring cranioplasty reconstruction can result from a variety of etiologies that require neurosurgical intervention for intracranial pathology. These include decompressive craniectomy to control acutely elevated intracranial pressure from intractable cerebral edema caused by ischemic stroke or cerebrovascular accident, traumatic brain injury, and aneurysmal subarachnoid hemorrhage. Other indications include bone flap infections and

* Corresponding Author's Email: cgordon@jhmi.edu.

resorption, and tumor involvement of the calvarium [1, 2]. Options for cranial reconstruction include autogenous bone flap replacement and/or bone allograft, bridging with titanium mesh, and other customized implants made of various synthetic biomaterials. In cases of craniectomy performed for cranial tumors, postoperative radiation and susceptibility to infection from immunosuppression may result in permanent bone flap removal and loss [1]. The principal goals of craniofacial reconstruction are to protect the underlying brain, restore symmetrical craniofacial contour, and prevent neurological dysfunction associated with the absence of bone flaps, such as “sinking skin flap syndrome” or “syndrome of the trephined”. The headaches and neurological deficits associated with Syndrome of the Trephined are postulated to result from four mechanisms: craniocaudal cerebrospinal fluid (CSF) flow inhibition, venous congestion, atmospheric pressure effects, and alterations in various cellular mechanisms [3]. Therefore, post-craniectomy CSF circulation abnormalities may be symptomatic, as described below [1-9].

TIMING OF CRANIOPLASTY

The timing of cranioplasty largely depends on the factors that led to initial craniectomy. The reasons for craniectomy can be classified into four categories:

1. Craniectomy required for the purposes of increasing the available space for brain expansion, e.g., following trauma or cerebrovascular accident.
2. Craniectomy required as a result of neurosurgical intervention to address brain or skull pathology.
3. Craniectomy required as a result of infection, including bone flap osteomyelitis.
4. Craniectomy required due to resorption of a patient’s native bone flap without evidence of infection or bone flap osteomyelitis.

In cases of trauma, decisions regarding the timing of cranioplasty should be guided by the amount of residual brain edema as determined by both clinical and radiographic examinations [10, 11].

With respect to “early” versus “late” cranioplasty, several studies have described the risks and benefits of each approach [12-15]. In cases of patients undergoing craniectomy for reasons other than surgical site infection, multiple studies have found that “early” cranioplasty (in some cases during the same admission) has several beneficial effects. Among these are provision of brain protection, improved vascular and CSF circulation, improved appearance, and the potential avoidance and/or reversal of complications such as Syndrome of the Trephined, which is marked by a significant deterioration of neurologic function after craniectomy that subsequently improves following cranioplasty [3, 12-16].

In a 10-year retrospective study of 157 patients comparing early (<12 weeks) versus late (>12 weeks) cranioplasty in the setting of trauma, the infection rate was lower (7.7% vs. 14%, respectively) in the early cranioplasty cohort. Bone graft resorption was also lower in the early cranioplasty cohort (15% early vs. 19% late), while complications such as hydrocephalus (7.7% early vs. 1.3% late) and postoperative hematoma (3.9% early vs. 1.3% late) were higher in the early group [14].

These differences, however, were not found to be statistically significant, and an overall complication rate of 35% was found in both early and late cranioplasty cohorts [14].

In another study comparing early versus late cranioplasty in the setting of craniectomy following hemorrhagic stroke, the overall complication rate was higher in the early cohort (22% vs. 16%), but this difference was not statistically significant ($P = 0.5541$) [15]. The early cohort in this study had a higher, but not statistically significant, rate of postoperative infection.

For cranioplasty performed in the setting of prior infection, the timing of reconstruction should be delayed until a full course of the appropriate, culture-directed intravenous antibiotics has been completed and all clinical signs of infection have resolved.

Typically, a waiting period of 3 to 12 months has been advocated before attempting cranioplasty in the setting of prior infection or bone flap osteomyelitis, depending on the isolated bacteria and/or fungus [17, 18]. A retrospective study by Lopez et al. looking at time-interval reduction for delayed implant-based cranioplasty found that the overall infection rate (4%) was similar in the early ($< 90 - 179$ days) and late (> 180 days) cranioplasty groups; with only one infection occurring in the late cranioplasty group out of a total cohort of 25 patients [17]. It is important to note, however, that microbial profiles, treatment, and resistance patterns may be hospital specific, and certain infections may require a longer (6 to 12 months) waiting period before implant-based cranioplasty is safely attempted.

Overall, early cranioplasty seems to have several benefits with little or no increase in complications according to published data [3, 14-16, 19]. For this reason, we concur that cranioplasty should be performed as early as possible once brain edema has resolved and it is safe to proceed, for the benefits described above. Furthermore, timely cranioplasty serves to avoid the contracted sunken scalp that may be problematic from a reconstructive standpoint in the event of delay.

However, the newly developed “pericranial-onlay technique,” as described by our group, mitigates this problem by providing additional scalp laxity and multilayer component release [20, 21].

CRANIOPLASTY TECHNIQUE

The initial approach to cranial reconstruction starts with a physical examination. It is important to thoroughly assess for scalp irregularities, open wounds with scabs, areas of alopecia, and previous surgical incisions. Fine-cut computed tomography (CT) of the cranial defect is necessary to assess the underlying skull defect (Figure 1) and potential for co-existing soft tissue atrophy [22]. If the patient’s own bone is unsuitable for use because of a history of infection, damage secondary to trauma or tumor, resorption, or a long time-lag between craniotomy and cranioplasty, a computer-designed customized cranial implant can be made of either poly-methylmethacrylate, porous polyethylene, or polyether ether ketone, the common materials of choice.

By utilizing 3-D printing technology and a revised algorithm described by Zhong et al. [22], the implants can be fashioned to match the exact dimensions of the pre-operative skeletal defect, as well as the accompanying temporal soft tissue atrophy including muscle

and/or fat. The next step would be to call on a vendor who can reliably design and fabricate a customized cranial implant using CAD/CAM technology [1].

Figure 1. A, preoperative CT analysis in red for modified implant shape vs blue outline replicating CCI designed to match the skull. B, virtual 3-D modeling with 2 overlapping designs. C, postoperative CT 2-D analysis showing modified implant in correct position. D, preoperative photograph right pterional craniectomy defect (arrow). E, 3 months after standard CCI cranioplasty showing severe persistent temporal hollowing (arrow). F, 3 months after modified CCI cranioplasty showing ideal cranial contour without temporal deformity (arrow). CCI, customized craniofacial implant.

In addition to providing the missing skull component, compensating for the amount of soft tissue loss in the temporal region is crucial, as cranial implants designed without accounting for temporalis muscle and fat pad atrophy will result in an obvious visual deformity known as “temporal hollowing” or “temporal wasting” [22]. In fact, some authors have reported an incidence of post-neurosurgical temporal hollowing that approaches 50% [23]. The visible asymmetry caused by temporal hollowing is commonly noticed by patients following craniotomy [22].

Obtaining a history of prior infection, radiation, or multiple surgeries should be performed as this can affect the quality of soft tissue coverage of the skull, and may require additional surgical planning with regard to implementation of component separation and/or rotational flap(s) to ensure a tension-free scalp closure with healthy tissue over the planned

reconstruction [21]. Tension-free closure is essential to a durable closure. The physical exam should also assess the quality of the scalp and nearby tissue, and try to determine whether there are any open wounds or scalp defects that may require scalp debridement and/or replacement, with delayed cranioplasty reconstruction to follow.

Preparation of the Surgical Site

Given the high morbidity associated with surgical site infections of the scalp and cranium, it is the practice of the senior author (C.G.) to be present for, and to directly participate in, surgical site sterilization and draping. While these tasks could be delegated to operating room staff or surgical trainees, techniques and consistency with respect to the task of surgical site sterilization may vary greatly, and thus it is in the surgeon's best interest to ensure that this crucial step of the procedure is performed judiciously.

Before surgery, the patient is informed that the majority, if not all, of the hair may require shaving in order to precisely determine the exact location of prior incisions. After shaving, the scalp is scrubbed with iodine solution. This is followed by a wet iodine-based surgical prep; and after demarcation of the surgical site with sterile towels, one last surgical site preparation is performed.

After preparation, all prior incisions are marked with a surgical marker and the bony defect is demarcated using hash marks (Figure 2). A 50:50 mixture of 1% lidocaine with epinephrine and sterile saline is injected into the scalp outside the confines of the cranial defect with care taken to inject away from the cranial defect and underlying brain.

(Hagerstown). 2014;10(0 2):179-190. doi:10.1227/NEU.0000000000000296. Oper. Neurosurg. (Hagerstown) | Copyright © 2014 by the Congress of Neurological Surgeons.

Figure 2. Skin markings used to denote the previous neurosurgical incision (solid line) and the large calvarial defect (dotted line) after infected bone flap removal.

Once the local anesthetic has had a chance to take effect, a #15 blade is used to make a partial thickness incision, just deep to the dermis and bulbs of the hair follicles, along the patient's prior incision. Needlepoint cautery is then used to complete the incision. Wide undermining of the entire scalp is then performed with a periosteal elevator to ensure scalp mobility and a tension-free closure. Once the incision has been opened and the scalp fully mobilized over the skull, the scalp overlying the brain is carefully dissected in a subgaleal plane with care to leave the pericranial tissue on the brain (avoiding the epidural plane) dura, as we previously described elsewhere [20]. When performing this step, it is important to remain in the proper dissection plane to avoid durotomy and brain injury by deviating too deeply and/or to compromise scalp perfusion by dissecting too superficially into the scalp's subdermal plexus.

Figure 3. Frontal view (A) and right profile view (B) of the original presentation with bone flap osteomyelitis. Aerial view (C) of the patient two weeks after removal of infected bone flap. Cephalad (D) on-table view before secondary cranial reconstruction 4 months after the bone flap removal. Photograph of vascularized pericranial-onlay dissection covering the dura (E) before inseting of the custom cranial implant with plates and screws (F). Postoperative 3-dimensional computed tomographic scan demonstrating the relative size of the implant, drain placement, and large amount of accompanying soft tissue reconstruction required with temporalis reinsertion (G). Frontal view photographs at the time of bone flap infection (H), at 3 months after bone flap removal (I), and at 6 months after reconstruction demonstrating acceptable contour and temporal symmetry (J).

These techniques should produce very little blood loss, and transfusions are almost never required for extradural cranial reconstruction.

Implant Placement

After the scalp has been elevated over the brain, the borders of the cranial defect are more clearly defined by removing scar tissue from the edges with electrocautery and periosteal elevators. The customized cranial implant is then checked to ensure proper fit, and it is customized on a side table if necessary prior to rigid fixation. Once the fit has been refined, the implant is fixed in place with titanium hardware (Figure 3). Suction drains are then placed and the scalp is closed in three layers with the galeal and subcutaneous layers closed with 3-0 absorbable suture, and the skin closed in interrupted fashion with nylon suture. A head wrap is then placed and remains in place for 2 to 3 days. Suction drains are monitored for output and removed at an appropriate time. A CT of the head and face is obtained the night of surgery to assess for significant brain edema, hematoma, or pneumocephalus since rare cases of “malignant cerebral edema” following cranioplasty have been reported [10, 11].

POSTOPERATIVE CARE

Following cranioplasty, admission to the intensive care unit is often unnecessary if the dura has not been violated, although this decision can vary greatly by institution based on the familiarity of the nursing staff with the care of cranioplasty patients. Patients typically are discharged on postoperative day 3 and return for suture removal after 3 to 4 weeks to allow time for healing of the thick scalp tissue. Sutures may remain in longer if the patient has other factors that could impair wound healing such as multiple prior surgeries, systemic illness, or history of radiation.

University of Maryland Medical Center, Baltimore, MD, US

ABSTRACT

Decompressive craniectomy (DC) can be a life-preserving procedure, but it is not without risk. Some complications develop during the immediate postoperative period, while others characteristically occur remote from surgery. Overall, complications of the initial craniectomy, as well as the cranioplasty that routinely follows, occur in approximately 20% of patients undergoing DC [1]. This chapter provides a synopsis of the common complications that follow DC, as well as the expected incidence, time course, and possible interventions.

Keywords: complication, decompressive craniectomy, traumatic brain injury, hygroma, resorption

INTRODUCTION

Decompressive craniectomy (DC), as described in other chapters of this volume, can be performed for a variety of indications including brain swelling resulting from traumatic brain injury (TBI), malignant cerebral infarction, and infection. DC remains the most effective, albeit drastic, means of reducing intracranial pressure (ICP) and alleviating midline shift [2], but depending on the patient, it may precipitate unique perioperative complications, including expansion of existing hemorrhage(s), severe alteration in cerebrospinal fluid (CSF) dynamics, or infection [3-6]. Some of these occur almost immediately. The important potential

* Corresponding Author's Email: gschwartzbauer@som.umaryland.edu.

complication burden of DC should be kept in mind when discussing patient care with family members as well as other health care providers. In this chapter, we provide a description of the common complications following DC, with an emphasis on those that are relatively unique to this surgery and may require further surgical intervention.

MECHANICAL EFFECTS OF DC

A common complication of DC results from the mechanical effect of decompression on the brain itself. Following DC, the edematous brain often herniates through the craniectomy defect, leading to neuronal stretch injury as well as compression of cortical vessels, which in turn can produce a secondary ischemic insult [3, 7]. Performing a decompression that is at least 12-cm wide may limit this process, though it is still frequently observed [3]. Brain herniation through the craniectomy defect has been proposed as one of the explanations why a randomized trial of bifrontal DC failed to show benefit [8].

In a series of 108 patients who underwent DC for TBI, nearly 28% demonstrated brain herniation through the craniectomy site [6]. This process may play a major role in the mixed outcomes that follow DC, as the ipsilateral hemisphere may experience up to 120% strain, with the brain tissue stretched by a factor of 2.2 times its resting length [7]. Interestingly, the contralateral hemisphere also shows evidence of significant strain. Rapid stretching of neurons to a strain of even 10% has been shown to induce neuronal damage, though the effects on individual neurons in the setting of DC remain unclear. A large part of this herniation event is thought to be driven by edema, and both clinical and preclinical studies suggest a large increase in brain water content at the DC site [7, 9]. Regional edema may be explained by the fact that microvascular dysregulation is present for several hours following a craniectomy. Cerebrovascular pressure reactivity (PRx), which is a correlation coefficient showing the relationship between ICP and mean arterial blood pressure (MAP), remains positive for hours postoperatively, reflecting impaired cerebral autoregulation and resulting in hyperemia and increased swelling [10, 11].

HEMORRHAGE

Blood products are toxic to brain tissue [12]. Unfortunately, intracerebral hemorrhage, including progressive secondary hemorrhage, may occur following DC. The mechanisms that underlie this phenomenon remain incompletely understood. Current management is preventive and consists of correcting coagulopathy and controlling blood pressure. Physicians must be aware of the potential for this complication, as intracerebral hemorrhage may bring about a return to the operating room for evacuation, particularly if the lesion compresses the basal cisterns or causes significant midline shift [3].

DEVELOPMENT OF IPSILATERAL OR CONTRALATERAL HEMORRHAGE

One of the most common complications following DC involves hemorrhage that is either ipsilateral to the DC or alternatively in a remote or contralateral location. Kurland et al., found that over 10% of patients who undergo DC develop new ipsilateral blood in some form, whether it is epidural, subdural, or intracerebral [1]. TBI patients have the highest likelihood of ipsilateral hemorrhage following DC, perhaps indicating underlying trauma-related coagulopathies, disrupted vessels, or contusion expansion. Thus once the swollen brain has been decompressed, meticulous attention to wound hemostasis is essential. These bleeds can result in a high rate of immediate reoperation [13].

Contralateral or remote hemorrhage (Figure 1) following DC remains one of the most vexing problems facing the surgeon and patient. The majority of these tend to occur in TBI patients, and are thought to reflect the release of a tamponade effect on injured vessels that may not be apparent on initial imaging. This mechanism results in an early rebleed pattern, and warrants close-interval radiographic follow-up after DC [1, 3].

Figure 1. A 29-year-old victim of civilian gunshot wound to the head was admitted to the Trauma Resuscitation Unit stuporous, a GCS motor score of 4 and reactive pupils. CT scan of head (plate A) revealed a perforating injury of right frontal bone and evidence of left sided subdural hematoma. The patient had an urgent DC following evacuation of the SDH. Postoperative CT scan (plate B) revealed a large epidural hematoma which was evacuated in association with debridement of the entrance wound. The patient remained moderately disabled. Plate C indicates cranioplasty 3 months following original DC (Courtesy of G Schwartzbauer, University of Maryland).

DC is also associated with the risk of progressive enlargement of hemorrhagic cerebral contusions, a process commonly referred to as progressive secondary hemorrhage or hemorrhagic progression of a contusion (HPC) [14]. This finding occurs in 13% of patients undergoing decompression [1]. While there are proposed molecular mechanisms that contribute to delayed HPC [15], it is thought that immediate HPC in the setting of DC, especially of large lesions, results from the removal of the tamponade force supplied by the skull. The resulting decrease in tissue pressure is hypothesized to allow for expansion of the volume of hemorrhage. Notably, while TBI patients on anticoagulants or antiplatelet agents requiring DC may be at increased risk of HPC, not all of these patients progress, and in some

studies no association has been shown [14]. Thus, often delayed contusion expansion may be the result of an orchestrated breakdown of vessels within the sphere of traumatic injury, and not simply leakage resulting from primary vascular rents. One promising molecular mechanism involves the activation of the Sur1-Trpm4 ion channel that leads to capillary fragmentation over several hours (see Chapter 1 by Simard and colleagues, for example).

HEMORRHAGIC TRANSFORMATION OF AN ISCHEMIC STROKE

Following DC for malignant MCA infarction, some patients experience hemorrhage into the ischemic stroke bed. Based on a recent review of the literature, the incidence appears to be approximately 24% [1]. The high rate of hemorrhagic transformation in DC patients likely reflects the known association between infarct size and hemorrhagic transformation [16], and a prospective study of 1125 consecutive ischemic stroke patients found an approximately 9% rate of transformation [17]. The clinical significance of hemorrhagic transformation remains controversial, potentially because of inter-study variability in the definition of hemorrhagic transformation [18]. Regardless, increased vigilance for postoperative hemorrhagic transformation should be maintained.

HYGROMA

Approximately 1 week after DC, some patients begin to develop subdural hygromas [19]. Subdural hygromas may form in as many as 30% to 50% of patients undergoing DC for severe TBI [19, 20]. In nearly 90% of cases, hygromas form on the side that is ipsilateral to the craniectomy (Figure 2); however, contralateral hygromas are also observed in a minority of patients [19]. The underlying mechanism of hygroma formation remains under investigation, but hygromas may result from aberrations in CSF flow that result from either the initial injury, the craniectomy, or both. The incidence of subdural hygroma formation peaks at 3 to 4 weeks, and then begins to decline, with ultimate resolution by 4 to 5 months postoperatively [19]. Aarabi et al., (2009) found that approximately 10% of patients with hygromas required a surgical intervention in the form of drainage. Therefore, close observation is warranted, though the vast majority of hygromas are benign collections that are self-limited.

Hygromas have also been documented in the setting of DC for stroke, occurring in approximately 12% of patients [1], though some studies report significantly higher numbers [21]. In one series, these collections were noted within 3 to 5 days following surgery, and disappeared within approximately 8 weeks. None of the patients in this series required surgical intervention for drainage of these collections [22]. However, the time course of subdural hygroma formation and resolution is not as thoroughly characterized in the stroke literature as in the trauma literature.

While most hygromas are benign, conversion to a subdural hematoma has been documented in some cases, which can require surgical intervention [19]. Thus, interval imaging should be obtained to verify resolution of the hygroma.

HYDROCEPHALUS

Patients commonly experience aberrant flow of CSF following DC, resulting in hydrocephalus in some. The incidence appears to be 15% of patients undergoing decompression for TBI and 26% of patients undergoing decompression for ischemic stroke [1]. These numbers are difficult to interpret, however, as authors do not always use consistent criteria to define hydrocephalus. In the case of decompression for stroke, in particular, post-decompressive hydrocephalus remains controversial. Many published series are plagued by small case numbers, making it difficult to draw generalizable conclusions [23, 24]. Compounding this difficulty, many authors often use only radiographic criteria, such as progressive enlargement of the ventricles and effacement of CSF spaces on head computed tomography, to diagnose hydrocephalus, particularly in patients who are neurologically devastated [24-26].

Opinion varies regarding the root cause of this complication. Some investigators have found that more severe brain injuries are associated with an increased risk of hydrocephalus [26]. Others have noted that the development of subdural hygromas in the postoperative period may predict the development of hydrocephalus [26, 27]. Still others have found that large bone flap margins that closely approximate the midline of the cranial vault also raise the risk of hydrocephalus [25, 27, 28].

Of note, ventriculomegaly secondary to cerebral atrophy (also known as hydrocephalus ex vacuo) is common in both trauma and stroke and likely results from the loss of neuronal substrate that follows both pathologies. This may result in enlargement of the lateral ventricle ipsilateral to the injury, with contralateral, third and fourth ventricles that are normal in size [24]. Hydrocephalus ex vacuo does not benefit from surgical intervention. In contrast, true hydrocephalus is both a radiographic and a clinical diagnosis, one component of which is ventriculomegaly. The diagnosis, however, should also include some constellation of progressive enlargement of the ventricular system, neurological decline/arrest of improvement, documentation of an elevated opening pressure by lumbar puncture, and improvement in neurological function following removal/diversion of CSF.

In patients requiring a cranioplasty and permanent CSF diversion (e.g., via a ventriculoperitoneal shunt), our own institutional practice is to perform the cranioplasty first. A ventricular tap may be performed intraoperatively as needed to replace the bone flap. We feel that placing a shunt at the time of the cranioplasty encourages the formation of a potential space between the bone and dura which could fill with blood or fluid. Allowing permissive hydrocephalus in the immediate postoperative period seems to alleviate this problem. Patients are then monitored closely for ventricular enlargement prior to discharge, and again at a follow-up appointment 2 to 6 weeks after the cranioplasty. As above, ventricular enlargement, particularly in the presence of neurological decline, is regarded as an indication for placement of a shunt. Staging these procedures has resulted in decreased rates of complications [29].

SYNDROME OF THE TREPHINED

The syndrome of the trephined was first described in 1939 by Grant and Norcross in their publication regarding the history and indications for cranioplasty [30]. The symptoms they

cited included headache, dizziness, fatigue, discomfort at the craniectomy site, general feelings of anxiety, depression, and “intolerance to vibration.” Other authors have added to the list of symptoms, which has become so extensive that some have argued that the syndrome should encompass any neurological symptom that improves rapidly following cranioplasty [31].

Syndrome of the trephined can be most consisely defined as the symptomatic deformation of brain tissue owing to its exposure to atmospheric pressure. Symptoms are most commonly present when the patient is in the upright position and are alleviated when the patient is supine or in a Trendelenberg position. The sunken flap overlying the cortex can compress the brain tissue and cause neurological deficits [32, 33] due to either direct compression or a decrease in cerebral blood flow secondary to compression [34]. Additionally, ICP may be paradoxically elevated in the upright position. In patients with an intact skull, the ICP should decrease when they are sitting upright; in patients with a craniectomy, the ICP will equalize with atmospheric pressure, thus producing an increase in ICP in the upright position [31]. Treatment of syndrome of the trephined involves replacement of the bone flap.

BONE FLAP RESORPTION

Most patients undergoing DC are expected eventually to undergo cranioplasty. This is commonly performed with autologous bone, which can be stored in the patient’s abdomen or in a freezer, depending on the institutional practice where the index procedure was performed. While not strictly a complication of DC itself, bone flap resorption is common and costly, and results in repeat presentations following decompression.

Figure 2. 21-m was admitted to the STC following MVC with a GCS of 7, abnormal pupillary response on the right side and a CT scan of head which was compatible with diffuse injury III (plate A). Medical management for control of ICPs failed 2 days later, therefore he had decompressive craniectomy (plate B). Eight weeks following craniectomy he manifested a large right sided subdural hygroma which was treated conservatively (plate C). Twelve weeks following trauma he had cranioplasty (plate D) and new CT scan bone windows two years following cranioplasty (plate E) shows extensive resorption of right parietal bone. The patient’s clinical outcome was severe disability. The patient was able to follow simple commands. (From Aarabi et al, Unpublished data). (Courtesy of G Schwartzbauer, University of Maryland).

Bone resorption following cranioplasty occurs in approximately 16% of cases [1] (Figure 2). Resorption appears to be more common in younger patients [35-37]. The need for shunt placement secondary to hydrocephalus and fragmentation of the bone flap into multiple pieces have also been identified as risk factors for bone resorption [36, 37]. Some authors have gone so far as to suggest that artificial graft material should be used for all patients under 30 years old, as well as older patients with compound fractures and/or hydrocephalus [37].

Several synthetic materials are available as an alternative source for cranioplasty, with options including polymethylmethacrylate (PMMA), polyethyl-ethyl-ketone (PEEK), and titanium. These materials have inherent advantages and disadvantages, which are beyond the scope of this chapter. Often, the material used is based on surgeon familiarity and preference. Future directions of research in this field will likely include a cost analysis of proceeding directly to synthetic implantation in patients at high risk for resorption.

CSF LEAKAGE, WOUND HEALING, INFECTION

A variety of complications that are noted following cranial procedures in general are of particular concern following DC. Leakage of CSF can lead to meningitis and may require CSF diversion in order to facilitate wound healing [1, 38, 39]. In addition, wound healing itself is a common complication of DC. This likely results from the use of a relatively large scalp flap in the presence of a relatively small vascular pedicle. Furthermore, the superficial temporal artery is often ligated during surgical exposure, further compromising the blood supply to the scalp flap [40].

While superficial infections, i.e., those involving the skin superficial to the galea, can often be treated with local wound care with or without a short course of antibiotics, infections involving the intracranial compartment result in significantly more morbidity. Deep infections reportedly occur in 2% to 6% of cases, depending on the indication for decompression [1]. Deep infections typically require surgical intervention in order to obtain cultures, wash out the infectious material, and achieve local source control.

CONCLUSION

Were one to compare DC with any number of elective neurosurgical procedures, the complication profile would likely be deemed unacceptable. However, DC is often the final option for preserving life in patients with large hemorrhagic or ischemic strokes, or in those with severe TBI and refractory intracranial hypertension. For this reason, a risk/benefit analysis by the clinician will often favor performing surgery despite the significant complication profile. That said, patients' medical decision makers must be made to understand the complications of DC since their risk/benefit analysis may differ from the clinician's. In addition, research must continue into the pathophysiology of hemorrhagic transformation or expansion, CSF flow abnormalities, and bone flap resorption, as these can be particularly morbid and possibly require further surgical intervention. While promising

medical therapies are under investigation that may reduce the need for DC, surgery and its attendant complications will persist for the foreseeable future.

ABSTRACT

The need to consider prognosis is important in all aspects of modern medicine, especially when there is a possibility that the eventual outcome may leave patients in a condition that they and their families may feel to be unacceptable. Decompressive craniectomy in the context of a neurological catastrophe represents a contemporary example of the clinical and ethical issues that can arise in these circumstances. Although surgical decompression can reduce mortality, it will not reverse the effects of the pathology that precipitated the neurological crisis, and the severity of the initial insult may be such that the most likely outcome is survival with severe disability. Since outcome prediction is necessarily limited, debate about the acceptability or otherwise of survival with severe disability is inevitable. However, discussions with family members cannot dichotomize outcome into life or death because to do so would fail to recognize that in certain circumstances the most likely outcome would be deemed unacceptable to the person on whom the procedure is being performed. The recently introduced ethical concepts of “substantive benefit” and the “risk of unacceptable badness” (“the RUB”) may be useful when considering a patient-centered decision regarding realistic outcome expectations.

Keywords: craniectomy, neurosurgery, prognosis, Glasgow Outcome Score, communication

INTRODUCTION

The need to consider prognosis is important in all aspects of modern medicine as progressively more complex decisions are required when considering increasingly sophisticated diagnostic and therapeutic interventions. However, despite these advances, there will always come a time when a disease has progressed to such an extent that either further therapy may be deemed overly burdensome or the eventual outcome may leave patients in a condition that they and their families may feel to be unacceptable. Decompressive craniectomy in the context of a neurological catastrophe such as severe traumatic brain injury (TBI) or malignant middle cerebral infarction represents a contemporary example of the clinical and ethical issues that can arise in these circumstances [1, 2]. Surgical intervention can undoubtedly reduce mortality, and numerous cohort studies have reported using the procedure, not only in the context of severe TBI [3-6] and stroke [7-10], but also, more recently, following subarachnoid hemorrhage [11, 12], intracerebral infection [13-15], venous sinus thrombosis [16, 17], and certain inflammatory conditions [18, 19]. However, evidence that functional outcome can be improved has been less forthcoming. This is probably because surgical intervention will not reverse the effects of the primary pathology that precipitated the neurological deterioration. For many years, the concern has been that any reduction in mortality will come as a result of an increase in the number of dependent survivors, some of whom may find this dependence to be an unacceptable outcome [20]. To address this issue, a number of randomized controlled trials were carried out in the past decade comparing surgical decompression with standard medical therapy, initially in the context of ischemic stroke [21-23] and more recently in the context of severe TBI [24, 25].

EVIDENCE FOR EFFICACY OF DECOMPRESSIVE CRANIECTOMY

The pooled analysis of the three European stroke trials published in 2007 established that in patients younger than 60 years, those having decompressive hemicraniectomy had significantly lower mortality than patients who received standard medical therapy [26]. The investigators also concluded that surgical decompression “increases the number of survivors with a favorable functional outcome.” However, reaching this conclusion was only possible by redefining the favorable outcome category to include patients with a modified Rankin score (mRS) of 4 [26, 27]. Indeed, the reduction in mortality came about as an almost direct increase in the number of patients with an mRS of 4, thereby confirming that surgical decompression increased the number of dependent survivors [27, 28].

These findings were further confirmed by the DESTINY (Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery) II trial that investigated decompressive hemicraniectomy in patients older than 60 years [29]. Among the twenty-five survivors in patients randomized to surgery, most were either mRS 4 or 5, and sixteen of these survivors had such severe aphasia or neuropsychological deficits that they were unable to answer a question about retrospective consent [28].

These ethically problematic findings have been confirmed by recent studies investigating decompressive craniectomy in the context of severe TBI [24, 25]. The Decompressive Craniectomy (DECRA) study confirmed the morbidity of the procedure by demonstrating that

despite reducing the intracranial pressure (ICP) and reducing time in intensive care, outcomes were worse in patients who underwent early surgical decompression. More recently, the findings of the RESCUEicp (Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of ICP) trial were consistent with the stroke trials in that the reduction came about by an almost direct increase in the number of survivors either in a vegetative state or with lower or upper severe disability [25].

There will always be debate about the definition of favorable outcome and the degree to which survivors can learn to live with severe disability [30, 31]. However, a time may come when the degree of neurological injury is such that the potential for functional recovery is limited and the most likely outcome, if the patient survives, is severe neurocognitive disability. In these circumstances, it is reasonable to consider withholding a “lifesaving” intervention because this is an outcome that most individuals would consider unacceptable. However, before this viewpoint can be adopted, several issues require consideration.

ETHICAL ISSUES RELATED TO THE POSSIBILITY OF CONVERTING DEATH INTO SURVIVAL WITH SEVERE DISABILITY

One of the first ethical issues related to lifesaving intervention is the difficulty in accurately assessing the severity of the pathological condition and thereby accurately predicting prognosis in those patients who require either a primary or secondary surgical decompression. Second, although most people may feel that survival with disability would be unacceptable, this is by no means always the case. Some individuals may feel that life is worth preserving at any cost, while others may be willing to risk severe disability in the hope that they may either eventually recover or perhaps learn to adapt and live with a level of disability that they might previously have thought to be unacceptable.

A third issue relates to consent and the role of surrogate decision makers. In most circumstances when consideration is being given to surgical intervention, because of the very nature of the pathological process, patients would have an impaired level of consciousness and would therefore have no competency to participate in decisions about their health care preferences. In these circumstances, relatives are often called upon to provide either known wishes or substituted judgment, which could raise further issues.

ASSESSING INJURY SEVERITY AND CONSIDERING PROGNOSIS IN TRAUMATIC BRAIN INJURY

For many years, the severity of the primary brain injury as adjudged by various clinical and radiological features has been recognized to have prognostic significance. Accordingly, ICP has been used to assess the developing secondary brain injury. However, the ICP has increasingly been acknowledged as a marker of end organ injury, and manipulation of the ICP is not necessarily converted into clinical benefit. Attempts have been made to develop other methods of monitoring secondary brain injury, but their clinical application in general neurotrauma practice has been relatively limited.

Assessment of the Primary Brain Injury

Traditionally, the Glasgow Coma Scale (GCS) has been used as a relatively reliable indicator of the severity of the primary injury as adjudged by the level of consciousness, and it is doubtless a robust assessment scale that has withstood the test of time. However, with the increasing use of prehospital intubation and ventilation [32, 33], its accuracy and reliability have been somewhat reduced [34, 35]. Other parameters having prognostic significance are age, pupillary reaction, presence of extracranial injuries, and certain radiological features on the initial computed tomography scan [4, 6, 36-38]. Although numerous prediction models have been developed that combine the predictive value of these clinical and radiological variables, most have been based on relatively small numbers with limited follow up and have tended to focus on survival as the primary outcome measure [39].

More recently, the availability of increasing amounts of accurate baseline data, combined with advances in statistical analysis, has enabled development of sophisticated Web-based prediction models that provide an accurate mathematical calculation of a prognostic risk [40, 41]. These models, based on large patient samples, have been both internally and externally validated. The CRASH (Corticosteroid Randomization after Significant Head Injury) collaborators' model was developed from the data collected on the 10,000 patients in the CRASH trial that investigated whether steroids were beneficial following TBI, and included mild, moderate, and severe TBI [42]. The clinical predictive variables required for the CRASH model are age, post resuscitation GCS score, pupillary response, and presence of a major extracranial injury. The radiological predictive variables are the presence of petechial hemorrhage, subarachnoid blood, midline shift, unevacuated hematoma, and obliteration of the basal cisterns.

Figure 1. The CRASH collaborators prediction model. The prediction of an unfavorable outcome at 6 months (x axis) and the observed outcome at 18 months among the 319 patients on whom 18-month follow-up was available. Numbers within the bar chart represent absolute patient numbers. (Reproduced with kind permission by Elsevier.)

Figure 2. The IMPACT investigators model. The prediction of an unfavorable outcome at 6 months (x axis) and the observed outcome at 18 months among the 319 patients on whom 18-month follow-up was available. Numbers within the bar chart represent absolute patient numbers. (Reproduced with kind permission by Elsevier.)

The IMPACT (International Mission for Prognosis and Clinical Trial) model was developed from 8509 patients and focused on patients with moderate and severe TBI [41]. The baseline presentation data differ slightly from that of the CRASH model. Only the motor function of the GCS is required, hypoxia and hypotension are recorded separately, and epidural mass is recorded as a separate radiological finding. The model also uses the Marshall radiological classification and incorporates the prognostic significance of presentation blood glucose and hemoglobin levels.

Both models are Web based and user friendly, and they provide a percentage risk of unfavorable outcome at 6 months (Figures 1 and 2). Unfavorable outcome is defined by the Glasgow Outcome Score (GOS) of severely disabled, vegetative, or dead [43]. Several studies have demonstrated how the prediction of an unfavorable outcome may be used as a surrogate index of injury severity with which patients can be stratified according to injury severity [44, 46]. Comparing the predicted risk with the observed long-term outcome can provide an objective measure of the most likely clinical outcome in those patients who require either a primary or secondary decompressive craniectomy. While the authors of both models emphasize that the information provided should only be used to support and not replace clinical judgment, the data certainly provide an objective assessment of the most likely outcome for those patients who require surgical intervention.

Assessment of Secondary Brain Injury via ICP

Use of ICP monitoring has become widespread over recent years as it provides important prognostic information. Studies have shown a strong correlation between outcome and the number of hours the ICP remains above 20 mm Hg, and this has been used as a threshold at which medical therapies are introduced in a stepwise protocol-driven manner [47-49]. These therapies include measures such as head elevation, further sedation and paralysis, drainage of

cerebrospinal fluid, and osmotherapy, followed by the judicious use of hyperventilation, barbiturate therapy, and hypothermia [49].

Despite this prognostic significance, one of the fundamental challenges in neurotrauma has been the inability to demonstrate that the reduction in ICP brought about by many of these therapies is necessarily translated into an improvement in clinical outcome [50-55].

For many years patients were routinely hyperventilated, placed in a barbiturate coma, or more recently rendered hypothermic. The rationale was that lowering the ICP improved clinical outcome. However, numerous clinical studies failed to demonstrate that these therapies achieve this objective and may, in certain circumstance, cause harm [53, 56]. On face value, these findings would appear counterintuitive; however, studies investigating the effect that these three therapies have on cerebral blood flow indicate a probable reason. Almost certainly, barbiturates and hypothermia have the potential to be neuroprotective owing to their influence on many aspects of the cellular response to injury, including calcium-mediated toxicity, glutamate excitotoxicity, free radical peroxidation, and cellular apoptosis [57, 59]. However, the mechanism by which these three therapies produce the often rapid fall in ICP that occurs after their application is predominantly a result of cerebral vasoconstriction, and the subsequent reduction in cerebral blood flow has been clearly demonstrated by a number of studies [60-62].

As demonstrated by the underlying pathophysiology and the compensatory mechanisms that occur when the brain swells, the last thing the swollen injured brain needs is less blood, and contemporary medical management aims to optimize cerebral perfusion and avoid secondary brain injury [49]. Currently, therapies such as hyperventilation, barbiturate coma, and hypothermia are generally reserved for intractable intracranial hypertension that is unresponsive to the aforementioned medical therapies.

In these circumstances, consideration is often given to decompressive surgery as it has also been shown consistently to reduce the ICP. Still, as with previous ICP-lowering measures, the results of recent studies have failed to demonstrate that the reduction is necessarily converted into clinical benefit. The DECRA study demonstrated that at the ICP threshold at which patients were enrolled (greater than 20 mm Hg for 15 minutes in an hour) there was insufficient ongoing secondary brain injury and therefore, notwithstanding the reduction in ICP that was observed in the patients randomized to surgery, any potential benefit in terms of improved cerebral perfusion was offset by surgical morbidity [24]. Given the ICP threshold, the absence of survival benefit in the patients in the surgical arm of the trial was unsurprising. The RESCUEicp trial demonstrated a clear survival benefit in those patients randomized to surgery at the higher ICP enrollment threshold; however, the reduction in mortality was consistent with the stroke studies in that this came about as an almost direct translation into survivors in either a vegetative state or with upper or lower severe disability [25].

These results would seem to confirm the limitations in using the ICP as a marker of injury severity in that it really represents a marker of end organ injury. Notwithstanding the prognostic significance of intractable intracranial hypertension, reducing the absolute number by either medical or surgical means will not reverse the effects of the pathology that precipitated the rise in ICP.

What is really needed is a more acute marker of the developing secondary brain injury, and a number of multimodal monitoring techniques have been developed in an attempt to address this issue. These modalities include microdialysis, monitoring brain oxygenation

either indirectly (as with jugular venous bulb monitoring) or directly (as with brain tissue oxygenation monitors), sophisticated bedside measures of autoregulation such as the pressure reactivity index or the mean index, and continuous electroencephalography monitoring [63].

Overall, despite significant developments in the availability and use of these techniques, the clinical significance of many of the recorded events remains undetermined. What is becoming increasingly apparent is that information obtained from a single modality that is interpreted independent from other physiological and metabolic parameters is unlikely to provide clinical benefit. In the same way that the CRASH and IMPACT models have combined individual prognostic indicators, what is now required are advances in real-time, user-friendly data analysis and presentation that can be used to guide appropriately targeted therapeutic management strategies. In addition, while the increasing complexity of monitoring technology must be matched with the appropriate clinical skills required to interpret the information gained, this is unlikely to improve outcome unless accompanied by new or improved therapies.

Predicting Long-Term Outcome in Ischemic Stroke

No such prognostic models are currently available for patients with other neurological pathologies. In the context of ischemic stroke, however, the DESTINY II trial confirmed the prognostic significance of age. Surgical decompression for those patients over 60 years of age is most likely to leave survivors fully dependent with severe neurocognitive deficits, and this outcome must be discussed with surrogate decision makers [29].

Other studies have demonstrated the prognostic significance of GCS on admission, involvement of territories other than the middle cerebral artery region, anisocoria, early clinical deterioration, coronary artery disease, and internal carotid artery occlusion and midline shift. Given the amount of outcome information available, possibly in the future similar prediction models may become available not only in the context of ischemic stroke but also for other pathologies, and while they should not replace clinical judgment, this type of methodology may help support discussions with family members.

COMMUNICATION WITH FAMILIES

Everyone has the right to make decisions regarding their health care preferences, and these decisions can differ substantially between different individuals based on personal, cultural, or religious values. Respect for these preferences is reflected in the importance placed on the need for informed consent prior to any medical or surgical intervention. This requires that individuals have a clear understanding of the facts, implications, and future consequences of an action and have sufficient reasoning faculties so that they are competent to make decisions [64-66].

When decompressive surgery for a neurological catastrophe is under consideration, these principles are challenged because the patients themselves will be in no position to participate in any discussion of treatment options. In these circumstances, family members are often called upon to assist in the decision making processes, and this can be ethically challenging. It

can place an enormous emotional burden on individuals whose competency to make decisions may already be compromised by emotional distress. The timing and manner in which these types of discussion take place may vary due to time constraints, situational circumstances, and available personnel, and there will never be a “one size fits all” approach. However, two key issues must be clearly established when communicating with families. First, the role of families in the decision making process must be clearly defined. Second, based on the aforementioned prognostic information, every attempt must be made to provide patients with an outcome that they would feel to be acceptable as opposed to overly burdensome.

THE ROLE OF FAMILIES IN THE DECISION MAKING PROCESS

Most discussions in the acute care setting are fraught with emotion and commonly result in statements such as “The family wants everything done.” However, adopting this position and acting accordingly can be ethically problematic because what is really being asked is whether the injured party would provide consent if it were possible to discuss the goals, risks, and outcome of the procedure. In addition, abandoning family members to make such a challenging decision in isolation is unfair. What is really required is a patient-centered discussion that guides family members through the decision making process and focuses on the *most likely* outcome after surgical intervention. These discussions must be based on either a patient’s known wishes (either documented or clearly stated) or substituted judgment regarding the acceptability or otherwise of that outcome, based on the individual’s personal values and preferences. If these are not known or if key stakeholders disagree, then discussions may focus on best interests. In these circumstances it may be possible to consider outcome using the recently introduced concepts of “substantial benefit” and the “risk of unacceptable badness” (RUB) in order to explore a more patient-centered view of the utility or indeed futility of surgical intervention based on an individual’s preferences.

“Substantial benefit” describes an outcome that the patient now or in the future would regard as worthwhile, recognizing that patients may adapt to a level of disability that they previously might have deemed unacceptable [67]. This observation is reinforced by the concept of the disability paradox that reflects the observation that many people with serious and persistent disabilities report a good or excellent quality of life when to most observers they would appear to live in a very undesirable state [68]. The counterpart of this condition is that of the RUB, which reflects the probability that a patient will end up living in a state that they would describe as intolerable [69].

The literary source of this term comes from Shakespeare’s character Hamlet who contemplates: “To sleep, perchance to dream, Aye, there’s the rub.” In the play, he has been told by a ghost that his uncle (who has since married his mother) murdered his father. Hamlet is considering revenge, but he realizes that if he acts on demonic information and commits a mortal sin, he will be damned. However, if he fails to avenge his father, he cannot live with himself. He then considers suicide and the release of eternal sleep, but he also contemplates the possibility that in death one dreams. The prospect of spending eternity dead, and therefore impotent, but wracked with the moral torments, is to him an unacceptably bad prospect. He therefore faces the RUB, the risk of falling into this unacceptably bad state [69].

In the context of decompressive craniectomy, these ethical concepts may be useful because notwithstanding the disability paradox, surgical intervention considerably increases the risk of survival within a state that fails to provide a person with substantive benefit and may be deemed unacceptable.

PROVIDING AN ACCEPTABLE OUTCOME

Before any decision is reached, acknowledgement should be made of the uncertainties in all fields of medicine and the grey areas in clinical decision making and health care preferences. Still, the actual decision to intervene surgically is a black and white choice, and the time comes when a decision has to be made.

Overall, three main categories of decisions require consideration: patients who have either stated, or for whom it was felt, that survival with severe disability would be unacceptable; patients for whom life is sacrosanct and worth preserving at any cost; and patients who have neither stated nor intimated their preferences or for whom there is disagreement or conflict among surrogate decision makers

Survival with Disability is Unacceptable

Somewhat abstract statements such as “I would rather die than live with severe disability” may or may not reflect a person’s thinking when actually faced with the possibility of disabling surgical sequelae. People have a right to make decisions about their health care preferences while competent to do so, and this forms the basis of advance directives, or living wills. These views must be respected and, whenever possible, acted upon. Surgeons may not reasonably assume that they have obtained consent to proceed with surgery if a person has previously documented, or stated, that he or she would not want to live with disability. Likewise, when relatives are asked “Knowing your relative as you did, would he or she be satisfied with survival with a serious disability?” and they state that their relative would find this to be unacceptable, then surgery should not be performed. This position is reinforced in the context of ischemic stroke for patients over 60 years of age or in the context of traumatic brain injury when the prediction of unfavorable outcome is greater than 80%. In these circumstances, the *most likely* outcome is severe disability. This must be fully reflected in discussions with family members who should not be made to feel that they are in any way burdened with making a decision; instead, the information should be provided so that the surgical team can act on a properly considered assessment of the wishes of the patient.

Survival with Severe Disability is Acceptable

Certain individuals may feel that life is sacrosanct and worth preserving at any cost, even if it means that they remain disabled and dependent. They would not view this outcome as unacceptably bad, but instead would feel that they would derive substantive benefit merely by being alive. This outlook may depend on a number of personal, cultural, or religious values,

and while it may not represent the majority view, whenever possible these values must be respected. When discussing these issues with families, care must be taken to determine that this is the viewpoint of the individual concerned and not the possibly unrealistic expectations of the family members who are hoping for a miracle cure. Similarly, while certain individuals may feel survival with severe disability to be unacceptable, they may be willing to take the risk of that outcome in the hope that they would either improve over time or adapt to a level of disability that they previously might have deemed unacceptable. It is in this regard that the data presented in Figures 1 and 2 may be useful for guiding discussions with family members.

The limitations of applying statistics obtained from large data sets to individual cases must be acknowledged. However, when considering a decompressive craniectomy in the context of acute neurotrauma, if the prediction of unfavorable outcome is less than 60%, it is unlikely (but not impossible) that the patient will be left severely disabled. Similarly, if this prediction is greater than 80%, the most likely outcome is either death or survival with either severe disability or in a vegetative state. If the prediction is between 60% and 80%, the outcome is truly uncertain, and this prognostic uncertainty must be a part of discussions about realistic outcome expectations.

Unknown Whether Survival with Severe Disability Would Be Acceptable

The largest and most challenging group of patients are those whose views on survival with severe disability are unknown. Most such patients are young and unlikely to have considered the possibility of themselves having to make such a decision about their preferences were such a neurological catastrophe to occur. Realistically, it would be very difficult not to proceed with surgical intervention for a young person in the context of ischemic stroke or severe TBI even if their prior wishes were not known and there was at least some chance of “substantive benefit” for that person. In talking with family members, the patient’s risk of survival with severe disability must be acknowledged and the acceptability or otherwise of this outcome must be directly confronted. Time constraints can make it difficult to fully explore alternative possibilities. Family members may be resentful if they are made to feel that the outcome of surgery was dichotomized into life or death with no mention of the possibility of survival with disability, especially if this is the eventual outcome. Similarly, if risk of an unacceptable outcome was acknowledged and accepted by those making the decision, surgical intervention can be justified even if the eventual outcome is indeed unacceptable. Clearly, the inevitable risks and uncertainties in all fields of medicine must be recognized by all those involved, especially those burdened with the decision making.

Decompressive craniectomy for the management of intracranial hypertension has been shown to increase survival in patients who have suffered catastrophic neurologic brain injuries. Whether the survival benefit translates into improved functional outcome is a matter of ongoing debate that continues to influence the application of this therapeutic option. In circumstances where a patient who has suffered a catastrophic brain injury has an advanced directive, goals of care are usually well defined with little room for ambiguity. Because of the acute and abrupt nature of these injuries, patients often do not have well-defined medical directives, thus requiring family members to provide substituted judgment on behalf of their loved ones. It is in these circumstances that we explore whether the acceptability of survival

with severe disability is indeed to the benefit of the patient within the context of overall quality of life. As we continue to expand our research into the field of therapeutic management of catastrophic neurologic trauma, it is important that we also strive to reconcile the need to increase survival in this patient population with the quality of life that the patients themselves would expect or desire.

ABSTRACT

The use of decompressive craniectomy for neurological emergencies continues to attract considerable interest, and evidence indicates that surgical intervention can reduce mortality. However, surgery will not reverse the effects of the pathological condition that precipitated the clinical deterioration. A concern has always been that many survivors will be left with severe disability and dependency, and some patients may consider this possibility unacceptable. A number of randomized controlled trials have attempted to address this issue, but their results have in many ways made the decision-making paradigm more difficult. They have confirmed unequivocally that mortality can be reduced; however, this has come at an *almost* direct translation into survival with severe disability. This finding raises several ethical issues regarding the definition of favorable outcome, the acceptability or otherwise of survival with severe disability, and wider issues regarding the allocation of health care resources.

Keywords: severe traumatic brain injury, futility, ethics

INTRODUCTION

Over the past three decades, interest in decompressive craniectomy has been considerable with numerous studies reporting its use, most commonly following severe traumatic brain injury [1–4] and ischemic stroke [5–8]. More recently, further cohort studies have reported use of the procedure in the context of subarachnoid hemorrhage [9, 10], intracranial infection [11, 12], and inflammatory conditions [13].

Overall, there appears to be little doubt that surgical intervention can lower the intracranial pressure and reduce mortality; however, it will not reverse the effects of the pathological condition that precipitated the clinical deterioration. For many years, the concern has been that many survivors will be left with a level of disability and dependency that they and their families may find unacceptable [14].

In an attempt to address this issue over the past decade, a number of prospective, multicenter, randomized controlled trials have investigated the efficacy of decompressive surgery, initially in the context of ischemic stroke [15–17] and more recently in the context of severe traumatic brain injury [18, 19]. The results of these trials have provided good evidence on which to base clinical practice; however, they have in some ways made the clinical decision-making paradigm more difficult, given the ethical issues that have arisen regarding long-term outcome and the acceptability or otherwise of survival with severe disability and dependency.

RESULTS OF THE RANDOMIZED CONTROLLED TRIALS

Decompressive Hemicraniectomy for Ischemic Stroke

In the early 2000s, three major trials conducted in Europe compared decompressive hemicraniectomy with standard medical therapy for patients under 60 years of age, who clinically deteriorated following the development of “malignant” middle cerebral infarction [15–17]. None of these trials were fully completed owing to difficulties with slow recruitment; however, each trial independently demonstrated that surgical decompression reduced mortality. Thereafter, a pooled analysis of the three trials found an “increase in the number patients with a favorable functional outcome” [20]. This finding appeared to provide unequivocal support for ongoing use of the procedure. Yet, closer examination of the study design raised concerns about a redefining of favorable outcome.

Traditionally, outcome following stroke has been assessed using the modified Rankin Scale (mRS), and favorable outcome has been defined as an mRS of 0–3. The implication of this definition seems to be that most people who recover want to have some degree of independence [21]. However, in the pooled analysis the favorable outcome category was changed to include patients with an mRS of 4. Favorable outcome therefore included patients who were highly dependent in that they could not walk unaided and could not attend to their bodily needs, an outcome that most investigators have previously deemed unfavorable [22, 23]. To justify this change, investigators asked patients who survived with severe disability whether they regretted having had surgery and whether they would have provided consent if

they had known their eventual outcome [15–17]. The relatively high levels of so-called “retrospective consent” were taken as justification for the recategorization.

An alternative interpretation of these positive responses, however, is that patients may have adapted to a level of neurological disability or recalibrated their preferences such that they now accept a level of disability that they might previously have deemed unacceptable. This phenomenon has previously been observed in the context of both stroke and severe traumatic brain injury, and it is certainly a testament to the human ability to survive and adapt to difficult circumstances [24, 25]. Still, we would contend that to accept this as a variation of the consent process and thereby validation of the surgical intervention is ethically problematic.

Informed consent, a fundamental tenet of modern medicine, requires that patients have a clear understanding of the facts, implications, and future consequences of an action *prior to* that action being performed [26, 27]. Furthermore, it requires that the patient be competent to make that judgment [28, 29]. While it must be acknowledged that there are significant limitations when a person makes somewhat abstract statements such as “I would rather die than survive with severe disability,” such assessments form the basis of documentation such as living wills and advance directives, and these views must be respected.

The finding that surgical intervention translates death into survival with full dependency was even more pronounced in the DESTINY II trial that investigated decompressive hemicraniectomy in patients over 60 years of age [30]. The trial confirmed that mortality was reduced from 70% at 6 months in those patients randomized to medical treatment down to 33% in those patients randomized to surgical decompression. However, the conclusion that “hemicraniectomy increased survival without severe disability” requires clarification given that only two patients (among the twenty-seven patients who survived following decompressive hemicraniectomy) achieved an mRS score of 3. The remaining twenty-five survivors were equally distributed between an mRS of 4 and 5. Furthermore, sixteen of these survivors had such severe aphasia or neuropsychological deficits that they were unable to answer a relatively simple question about retrospective consent [22].

Overall, the evidence is unequivocal that decompressive hemicraniectomy in the context of ischemic stroke almost uniformly translates deaths into increased numbers of survivors with severe disability and dependency. This must be thoroughly discussed with key stakeholders prior to considering surgical intervention. Similarly, evidence for this ethically problematic choice is now found in the context of severe traumatic brain injury.

Decompressive Craniectomy for Severe Traumatic Brain Injury

Numerous observational cohort studies have demonstrated that decompressive surgery can be used to control severe intractable intracranial hypertension in the context of severe traumatic brain injury [1–4]. Furthermore, two large multicenter randomized controlled trials have compared surgical decompression with standard medical therapy [18, 19]. The DECRA study investigated the role of early bifrontal decompressive craniectomy in the context of diffuse cerebral swelling. The hypothesis on which the trial was based was that early decompression would optimize cerebral perfusion and improve clinical outcome by reducing secondary insults. To examine this hypothesis, patients were randomized at the relatively low intracranial pressure (ICP) threshold of greater than 20 mm Hg for more than fifteen minutes

in the hour after first-tier medical therapy. Given this threshold, it was unsurprising that there was no survival benefit in those patients randomized to the surgical arm of the trial compared to those patients randomized to standard medical therapy. What was unexpected, however, was that despite consistently lower ICP and less time spent in intensive care, neurological outcomes at 6 months were worse in patients who had been randomized to surgery. The results of the study provoked considerable debate. One of the key criticisms was that the ICP threshold at which patients were randomized was not representative of current clinical practice (which is to intervene at higher ICP thresholds) [31]. With the benefit of hindsight, this is a valid observation, but if the trial had shown benefit, these patients would have come to represent the *clinical practice of the future*, which would have had a significant impact on neurosurgical practice, especially if survival (regardless of quality of life) were the only valued outcome [32].

The DECRA trial clearly, unequivocally demonstrated that, at that particular ICP enrollment threshold, the ongoing secondary brain injury was insufficient to justify surgical intervention and that any potential benefit obtained from improved cerebral perfusion was offset by the increasingly appreciated morbidity of the procedure [33]. Prior to these findings, it was almost assumed that lowering the ICP would be beneficial; however, in many ways these results have highlighted the need for more considered judgment when making surgical decisions [34].

The results of the RESCUEicp trial have provided even more evidence to inform the ethical debate [19]. The higher ICP enrollment threshold led to a significant survival benefit in those patients randomized to the surgical arm of the trial, and these results were consistent with the stroke trials. There were further similarities in that this reduction in mortality came as an almost direct result of an increase in the number of survivors either in a vegetative state or with severe disability. At 12-month follow up, there was a small increase, albeit statistically insignificant, in the percentage of patients with a favorable outcome—from 34.6% in the medical arm of the trial to 42% ($P = 0.12$) in the surgical arm of the trial. However, this small increase was only seen when the Extended Glasgow Outcome Scale category was changed to include upper levels of severe disability as favorable, in a similar fashion to the stroke trials that deemed an mRS of 4 as favorable. Without this recategorization, the percentage of patients who survived with lower moderate disability or better (traditionally regarded as a genuinely favorable outcome) was very similar (32% favorable in the surgical arm of the trial and 28.5% favorable in the medical arm). Furthermore, and perhaps of greatest concern, the number of survivors in a vegetative state increased. At 6 months, the number of vegetative survivors increased from 4 out of 188 patients (2.1%) randomized to the medical arm of the trial, to 17 out of 201 patients (8.5%) randomized to the surgical arm. This finding is even more ethically problematic when considering outcome findings at 12 months because apparently six of these patients who were in a vegetative state at 6 months subsequently died (five patients in the surgical arm and one patient in the medical arm). The psychological distress for families involved in these circumstances and the enormous financial costs to society should be balanced against the benefits for the patients surviving with lesser degrees of disability.

DECOMPRESSIVE CRANIECTOMY – RESULTS ANALYSIS

Compelling evidence now supports the ethically challenging conclusion that surgical intervention reduces mortality at the expense of an increase in survivors either with severe disability or in a vegetative state. These findings must be reflected in discussions regarding outcome following decompressive craniectomy because long-term outcome cannot be dichotomized into life or death. Indeed, to do so would fail to recognize that surgical intervention increases the likelihood of exposing patients to an outcome that they and their families may consider unacceptable. In addition, the time may have come for a more nuanced ethical examination regarding the ongoing use of a procedure that in a small but significant number of cases increases short-term survival in a fully dependent state at a considerable financial and psychological cost to society.

Overall, the results of the randomized controlled trials have provided good evidence on which to base clinical management; however, they have in many ways emphasized the need for more considered judgment to be exercised when making decisions regarding surgical intervention.

DECOMPRESSIVE CRANIECTOMY – FUTURE CONSIDERATIONS

Despite the evidence from the randomized controlled trials, certain individuals who undergo surgical decompression undoubtedly survive a life-threatening neurological catastrophe and either go on to make a good neurological recovery or adapt to a level of disability that they may previously have deemed unacceptable. The difficulty remains identifying those individuals who are most likely to derive clinical benefit. In the context of ischemic stroke, age is obviously an important factor, and it would seem reasonable to consider surgical intervention for young people, especially if their prior wishes are unknown, because they may learn to adapt to a level of disability that they may previously have thought to be unacceptable [24, 25].

This viewpoint is further supported by the ethical concept of the “rule of rescue” that describes the powerful human proclivity to rescue identified endangered lives, regardless of cost or risk [35]. Furthermore, people obtain considerable social utility and a feeling of security from knowing they live in a compassionate society that cares for the needs of each constituent member and where those in most desperate need will not be ignored or abandoned merely on the basis of resource allocation. However, this security can be threatened if the rescue system is seen to be a juggernaut that is insensitive to the way people actually value their lives. The DESTINY II trial clearly demonstrated the difficulty in invoking the rule of rescue for patients over 60 years of age given that most survivors will be immobile, unable to communicate, and fully dependent on nursing care.

In the context of severe traumatic brain injury, while age is an acknowledged important prognostic factor, several other clinical and radiological parameters have also been shown to significantly affect prognosis. Recent improvements in data collection and statistical analysis have enabled researchers to develop sophisticated Web-based outcome prediction models that provide a percentage prediction of unfavorable outcome at 6 months (defined by the Glasgow Outcome Scale as severe disability, vegetative, or dead) [36, 37]. The CRASH model

(Corticosteroid Randomisation after Significant Head Injury) uses the clinically predictive variables of age, post-resuscitation Glasgow Coma Scale (GCS), pupillary response, and presence of a major extracranial injury. The radiological predictive variables used are the presence of petechial hemorrhage, subarachnoid blood, midline shift, unevacuated hematoma, and obliteration of the basal cisterns. The baseline presentation data required for the IMPACT (International Mission for Prognosis and Clinical Trial) model differs slightly from that of the CRASH model. Only the motor function of the GCS is required, hypoxia and hypotension are recorded separately, and epidural mass is recorded as a separate radiological finding. In addition, the Marshall radiological classification is used, and the final part of the model incorporates the prognostic significance of presentation blood glucose and hemoglobin levels.

A number of studies have used the percentage prediction to stratify patients according to injury severity and compared the *prediction* of unfavorable outcome with the *observed* long-term outcome [38–40]. Presenting data in this manner provides an objective assessment of the *most likely* outcome following surgical intervention and can perhaps form the basis of a more rational and informed discussion among stakeholders when considering decompressive surgery (Figures 1 and 2).

Figure 1. The CRASH collaborators prediction model. The prediction of an unfavorable outcome at 6 months (x axis) and the observed outcome at 18 months among the 319 patients on whom 18-month follow-up was available. Numbers within the bar chart represent absolute patient numbers. (Reproduced with kind permission by Elsevier).

The decision to offer or undertake decompressive surgery, however, cannot rest solely on the preferences of the patients or their next of kin because of the important resource allocation issues related to long-term care for those who survive with dependency. It must, of course, be acknowledged there will always be limitations when attempting to predict long-term outcome, and from a purist's perspective, prognostic models should never be used to guide medical decision-making for individual patients. In addition, there will always be those patients who defy the odds and make a miraculous recovery despite seemingly desperate circumstances.

Inevitably, a time comes when these issues must be considered, as in the case of patients over 60 years of age with ischemic stroke or patients with a severe traumatic brain injury and a prediction of unfavorable outcome greater than 80%. In these ethically challenging

circumstances, the most likely outcome for survivors is either severe disability or survival in a vegetative state. The surgeon, therefore, has an obligation, both professionally and ethically, to establish whether this outcome would be acceptable for that individual. In addition, the larger community has to determine the value placed on a single individual's life at any and all (financial and non-financial) cost. The considerations here are not only financial but also personal and ethical, and they require us to exercise well-considered judgment about our actions.

Figure 2. The IMPACT investigators model. The prediction of an unfavorable outcome at 6 months (x axis) and the observed outcome at 18 months among the 319 patients on whom 18-month follow-up was available. Numbers within the bar chart represent absolute patient numbers. (Reproduced with kind permission by Elsevier).

In the fraught setting of an acute neurological deterioration, neurosurgeons are often called on late in the clinical scenario to perform lifesaving surgery, often with insufficient time for detailed discussion of realistic outcome expectations. In addition, families will often have compromised capacity (caused by emotional distress) to really consider the true implications of survival with severe disability, and their hopes for a miracle cure may be at odds with likely outcomes. Before approaching families to discuss the potential benefit or burden of surgical intervention, all medical and surgical stakeholders must reach a clear consensus. Such clarity will help ease the family's difficult decision-making regarding surgery.

Finally, given available evidence, the time may have come for policy makers and society as a whole to be more explicit regarding resource allocation and perhaps more openly discuss the limitations of our modern health care systems and the need to spend resources wisely [41].

CONCLUSION

In reality, the decision to perform decompressive craniectomy will always be challenging. There is now clear evidence that mortality can be reduced but that this reduction comes at the cost of an outcome some individuals consider unacceptable. In the context of

severe traumatic brain injury, the ongoing use and further refinement of high-quality outcome prediction models may provide an objective assessment of the most likely outcome following surgical intervention. No such models exist for decompressive hemicraniectomy in the context of ischemic stroke or other neurological catastrophes; however, given the amount of data available, this would not appear to be a particularly difficult undertaking.

It must be acknowledged that there will always be limitations when using population-based data on individual cases, but the objective assessment that they can provide may help prompt appropriate patient-centered discussions regarding realistic outcome expectations. Further work may be required to establish the role of decompressive craniectomy in other neurological emergencies. Given the evidence now available, however, a broader debate is needed on the use of a medical intervention that increases the number of survivors with either severe disability or in a vegetative state, survival that comes at what may be a considerable psychological stress to their families and financial burden to the society.

ABSTRACT

On October 9, 2017, in an open scientific session of the Congress of Neurological Surgeons on “Neurotrauma and Critical Care,” Drs. Shelly Timmons (Pennsylvania State University) and Martina Stippler (Harvard University) presented a lively debate *for and against* decompressive craniectomy.* In this session, Dr. Stippler presented the following scenario to the audience: “When the ICP threshold is alarming and life-threatening, who would proceed with decompressive craniectomy for severe traumatic brain injury?” The show of hands overwhelmingly supported decompressive craniectomy.

This systematic review appraises the existing body of literature, and focuses specifically on the prognostic value of traumatic brainstem injury (TBSI) on magnetic resonance imaging (MRI) studies in this clinical setting. Does MRI add to the predictive significance of the existing prognostic models? And should it therefore influence decision-making regarding decompressive craniectomy? In the following chapter, we review what has been conclusively written about the role of MRI in predicting neurologic outcome following traumatic injury to the central nervous system and provide a case report of our own.

A computerized search of the National Library of Medicine PubMed database of literature, applying multiple medical subject headings, yielded 734 citations addressing MRI and traumatic brain injury. Nine articles specifically reported the prognostic significance of TBSI and long-term outcome. Level II and III evidence indicated that the presence of TBSI on MRI was usually an indication of extensive rostral-caudal traumatic

* Corresponding Author’s Email: baarabi@som.umaryland.edu.

axonal injury and signified unfavorable outcome. In one Level II study, inclusion of MRI variables in the core model (age, pupillary dilatation, and GCS score) of Area Under the Receiver Operating Characteristics (AUROC)+ CT Rotterdam covariates increased the prognostic significance (GOSE ≤ 6 at 12 months) from 0.8287 to 0.8763.

Keywords: MRI, TBI, brainstem, outcome, decompressive craniectomy, GOSE

INTRODUCTION

Over the past 40 years histopathological and preclinical studies [2-6] have indicated that the translation of kinetic energy (stress/strain) following mechanical injury to the brain transpires in less than 200 milliseconds and disrupts the structure and function of the central nervous system in a centripetal fashion [2-16]. The Ommaya-Gennarelli hypothesis of diffuse brain injury, first reported in 1974 [6] in primate models of traumatic brain injury (TBI), articulated the principle that energy dispersion following trauma spreads from the cortex into the subcortical white, central gray, corpus callosum, mesencephalic-diencephalic junction, and brain stem in a graded rostral-caudal fashion. Less severe energy dispersion over the superficial cortex produced concussion; however, more extensive strain/sprain spread during angular acceleration/deceleration injuries resulted in coma or death [17, 18]. In a 1988 report, Levin et al. studied the magnetic resonance imaging (MRI) results of 94 patients with closed head injuries of varying severity and found that the depth of the lesions correlated positively with the degree and duration of altered consciousness, independently of secondary influences such as intracranial pressure and size of the lesion, thereby lending support to Ommaya and Gennarelli's original hypothesis [19]. This concept supports the notion that any evidence of traumatic brainstem injury (TBSI) on imaging studies may be an indication of more severe diffuse injury capable of substantial disruption of structure and function.

With the advent of computed tomography (CT) in 1976, Merino and Taveras reported visual representation of intracranial hematomas, brain swelling, and evidence of midline shift due to hematomas or brain swelling [20]. Marshall et al., in 1997, and Maas et al., in 2007, introduced CT classifications of severe TBI [21, 22] with high internal validity: area under the curve (AUC) = 0.77 [22, 23]. Approximately half of patients with severe head injury show evidence of intracranial mass lesions and the other half show indications of diffuse injury 1-4 on the Marshall Classification [24, 25]. Nevertheless, -because of bone artefact (low signal-to-noise ratio) and inadequate contrast and resolution, CT scan is weak in discriminating posterior fossa microhemorrhages or TBSI [25, 26].

In a prospective study of 40 patients with blunt TBI and a Glasgow Coma Scale (GCS) score ranging from 3 to 14, Gentry et al. found higher sensitivity of magnetic resonance imaging (MRI) in detecting focal and diffuse brainstem lesions with precise anatomical localization: superficial versus deep, dorsal versus ventral, and midbrain versus pons versus medulla oblongata [26]. While CT detected only 9.1% of TBSIs, the detection rate was 81.8% on T1 and 72.7% on T2 MRI. The superiority of MRI in detecting brainstem injuries has been recorded by other investigators [27-30]. MRI clearly depicts microhemorrhages on SWI (Susceptibility Weighted Image) and T2*GRE (Star Gradient Echo), diffuse injuries on FLAIR (Fluid Attenuated Inversion Recovery) and T2WI (T2 Weighted Image), and evidence of ischemic damage on DWI/ADC (Diffusion Weighted Image/Apparent Diffusion

Coefficient) sequences. Collectively, these represent the pathological hallmarks of traumatic injuries to central nervous system [28, 29, 31, 32]. Only two subjects in Mannion's cohort of 46 ventilated patients with severe head injury showed CT evidence of TBSI while MRI was capable of revealing evidence of TBSI in 13 patients [25]. In a prospective study by Lagares et al., only three of 100 patients had CT evidence of TBSI while MRI showed 33 patients with significant injury to the mesencephalon, pons, and medulla [33]. The incidence of TBSI on MRI of patients with severe TBI has ranged from 25% to 50% [25, 30, 34-37].

Acquisition of early multi-sequence MRI in a patient with severe TBI under controlled ventilation in the intensive care unit is often not feasible. Availability, cost, compatibility of life-support equipment, and safety of transportation are some of the hurdles to acquiring MRI studies for the purposes of TBSI evaluation [25]. In addition, inadequate support for the strength of association between TBSI and outcome and the time window available to complete the study make this imaging modality risky and impractical in some cases.

In this chapter, we questioned the level of evidence in previous studies on the role of MRI in predicting neurologic outcome in traumatic brain injury in order to further clarify the strength by which MRI might be recommended for evaluation of these patients. Specifically, we address the hypothesis that MRI enhances the predictive value of existing models for TBI and TBSI, and we conclude with a case report that address the prognostic capabilities of this modality and its role in the decision to pursue decompressive craniectomy in the setting of TBI/TBSI.

REVIEW OF THE LITERATURE

Search Criteria

To identify pertinent evidence, we performed a computerized search of the National Library of Medicine (NLM) literature database (PubMed) from 1990-2017, using the following medical subject headings:

- 1) "MRI AND TBI" — 734 citations.
- 2) "MRI AND TBI AND prognosis" — 156 citations.
- 3) "MRI AND prognosis after severe head injury" — 151 citations.
- 4) "MRI AND brainstem AND prognosis AND TBI" — 71 citations.

An additional search of the reference lists of identified publications yielded another 21 citations.

From these search results, we selected nine publications for this Systematic Review that offer the best evidence [25, 30-33, 36, 38-40].

Methodology

Figure 1 illustrates our methodology. Three reviewers independently read all the titles and abstracts of the 734 published articles identified in our original search. Then applying our

inclusion and exclusion criteria, they excluded 725, leaving nine studies. Full texts of these nine articles were appraised by the three reviewers for precision of the study design and directness of methodology; robustness of the data; details of the results; extent of statistical analysis; risks of bias; and interpretation of the results (Figure 1, Table 1).

Figure 1. Flow diagram indicating computerized search of National Library of Medicine (NLM) PubMed literature database from 1990-2017. (Courtesy of B Aarabi, University of Maryland).

DISCUSSION

Three Level II and six level III evidence citations from this Systematic Review bring several important concepts into focus:

- 1) Primary TBSI is distinguished from Secondary TBSI, the latter of which is thought to be due mainly from brainstem compression. Primary TBSI almost always is part of a more extensive traumatic process involving centripetal kinetic energy dispersion and parenchymal stress/strain. The neuropathological studies of Adams et al. and the primate models of diffuse axonal injury (DAI) reported by Ommaya and Gennarelli arrived at this conclusion decades ago [6, 12-14, 17, 18, 41, 42]. Since CT imaging is rather insensitive in imaging traumatic axonal injury (TAI), Compared with CT, MRI provides high spatial resolution with high signal-to-noise ratio, and at present remains the gold standard modality for detecting and characterizing traumatic axonal injury (TAI) involving the cerebrum and brainstem tegmentum [43-48].
- 2) In patients with severe head injury, functional outcome is dictated by the collective lesion load (volume and location) spread across the cerebral cortex, subcortical white, central gray, corpus callosum, and brainstem [32, 40].

Table 1. Strength of evidence

Study	Level	Years of Study	Patients	Level of Consciousness	Intervention	Outcome
Smitherman E J Neurotrauma 2016 [32] University Texas Southwestern USA	III (R)	2005-2012	63	Glasgow Coma Scale (GCS) <12 (5.6±3.9)	The researchers studied prognostic value of FLAIR hyperintense lesion load and location on the Pediatric Glasgow Outcome Scale – Extended (GOS-E Peds) outcome 13.5 months after trauma (favorable GOS-E Peds 1-4 and unfavorable GOS-E Peds 5-8). MRI field strength 1.5 or 3T). Hyperintense Lesion Volume Index (HLVI) was calculated for lesions involving cortex, central gray, and brain stem. Mean age was 9.9 (0-17) and the studies were performed a mean of 6.2 days following trauma (0-22 days). HLVI = HLVI / total brain volume×100	Distribution of FLAIR hyperintense lesions (FHLs) was in 3 zones: A=superficial cortex; B=corpus callosum, basal ganglia, and thalamus; and C=brainstem. Distribution of FHLs was in 3 patterns: A: superficial; A+B: superficial and deep lesions; and A+B+C: lesions in all 3 zones. Fifteen of 63 (24%) patients had TBSI, 14 of which were associated with more superficial lesions. Total FLAIR HLVI (P = 0.02) and brainstem HLVI (P = 0.024) predicted favorable and unfavorable outcomes, respectively. In adolescents, total FLAIR lesion volume correlated best with outcome; in children <13 y, deep lesion volume correlated best with outcome. Compared to patterns A and A+B, logistic regression testing of all injury patterns indicated that the A+B+C injury pattern was significantly predictive of unfavorable outcome (OR 4.38, 95% CI 1.19-16.0) P = 0.03. In addition to injury pattern A+B+C, HLVI-total (P <0.0001) was related to unfavorable outcome. The Relationship Between HLVI and Outcome (GOSE-Peds)
						Hyperintensity Lesion Volume Zones
						HLVI Zone A (cortical structures)
						HLVI Zone B (basal ganglia, corpus callosum, internal capsule, and thalamus)
						HLVI Zone C (brainstem)
						HLVI-Total

Table 1. (Continued)

Study	Level	Years of Study	Patients	Level of Consciousness	Intervention	Outcome																																																			
Moen KG J Neurotrauma 2014 Norwegian and St Olav Universities, Norway [40]	II (P)	2004-2009	128	GCS 3-12	FLAIR, DWI, and T2*GRE MRI sequences were used to measure the prognostic value of traumatic axonal injury (TAI) lesion loads in corpus callosum, thalamus, and brainstem and relate that to GOSE outcome at 12 months. The studies were within 8 days of trauma (0-28 days). The cohort's mean age was 33.9 years.	Among the severe head injury (SHI) patients, 19 (30%) had TBSI. After adjustment for age, GCS, and pupillary reaction, the TAI lesion load was an independent prognostic factor in patients with severe TBI (OR = 1.3-6.9, P <0.001) Multivariate Logistic Regression Models Predicting Outcome (GOSE) <table><tr><th>Region</th><th>OR (95% CI)</th><th>P</th></tr><tr><td>FLAIR (volume)</td><td></td><td></td></tr><tr><td>Whole brain</td><td>1.15 (1.06-1.25)</td><td>0.001</td></tr><tr><td>Corpus callosum</td><td>1.27 (1.08-1.49)</td><td>0.004</td></tr><tr><td>Brainstem</td><td>1.37 (1.06-1.77)</td><td>0.017</td></tr><tr><td>Thalamus</td><td>1.70 (1.22-2.36)</td><td>0.002</td></tr><tr><td>DWI (number)</td><td></td><td></td></tr><tr><td>Whole brain</td><td>1.10 (1.01-1.20)</td><td>0.25</td></tr><tr><td>Corpus callosum</td><td>2.67 (1.57-4.55)</td><td><0.001</td></tr><tr><td>Brainstem</td><td>3.06 (1.31-7.14)</td><td>0.010</td></tr><tr><td>Thalamus</td><td>6.87 (1.95-24.2)</td><td>0.003</td></tr><tr><td>T2*GRE (number)</td><td></td><td></td></tr><tr><td>Whole brain</td><td>1.02 (1.00-1.05)</td><td>0.055</td></tr><tr><td>Corpus callosum</td><td>1.01 (1.00-1.03)</td><td>0.16</td></tr><tr><td>Brainstem</td><td>1.01 (0.99-1.04)</td><td>0.36</td></tr><tr><td>Thalamus</td><td>1.17 (0.99-1.38)</td><td>0.07</td></tr><tr><td>Rotterdam CT score</td><td>1.47 (0.94-2.29)</td><td>0.88</td></tr></table>	Region	OR (95% CI)	P	FLAIR (volume)			Whole brain	1.15 (1.06-1.25)	0.001	Corpus callosum	1.27 (1.08-1.49)	0.004	Brainstem	1.37 (1.06-1.77)	0.017	Thalamus	1.70 (1.22-2.36)	0.002	DWI (number)			Whole brain	1.10 (1.01-1.20)	0.25	Corpus callosum	2.67 (1.57-4.55)	<0.001	Brainstem	3.06 (1.31-7.14)	0.010	Thalamus	6.87 (1.95-24.2)	0.003	T2*GRE (number)			Whole brain	1.02 (1.00-1.05)	0.055	Corpus callosum	1.01 (1.00-1.03)	0.16	Brainstem	1.01 (0.99-1.04)	0.36	Thalamus	1.17 (0.99-1.38)	0.07	Rotterdam CT score	1.47 (0.94-2.29)	0.88

Hilario A AJNR 2012 Hospital 12 de Octubre, Madrid, Spain [31]	III (R)	2002-2011	108	GCS <8	Geographic location (anterior, posterior, unilateral, and bilateral) of TBSI lesions and their association with GOSE 6 months following severe head injury were studied a mean of 17 days after trauma. The age of patients was 15–75 years. MRI field strength was 1.5 T; sequences were T1WI, T2WI, FLAIR, and T2*GRE.	Fifty-one of 108 (47%) patients had TBSI. Depth of lesion analysis indicated that subcortical lesions were present in 92% and injury to corpus callosum in 71% of patients with TBSI. Among patients with TBSI 66% had poor outcome. Bilateral (P <0.05), posterior (OR 6.8, CI 1.8-25, sensitivity 68%, specificity 76%) and hemorrhagic lesions had better discriminatory capacity for outcome than anterior, nonhemorrhagic, and unilateral lesions (P <0.05, OR 5.9, CI 1.6-22). A posterior, bilateral, and hemorrhagic lesion had the worst prognostic significance. On the other hand, nonhemorrhagic, unilateral and anterior lesions had the highest discriminatory capacity for good outcome. Chew BG J Neurosurg 2012 Alleghany General Hospital Pittsburgh, PA USA(39)	III (R)	2004-2012	36	GCS <8 in 24 patients	Early MRI (median 1 and range 0-35 days, Field Strength 1.5 T and sequences T1WI, T2WI, T2*GRE, FLAIR, DWI and ADC) were performed aimed at defining the prognostic value of MRI and traumatic lesion load at the brainstem. Mean age of the cohort was 45.5 years.	Nineteen (53%) patients had poor outcome, including 17 patients who died. Twenty-two TBSIs were at the level of midbrain, 17 at the level of pons, and two at the level of medulla. Lesion loads crossing the midline at the level of medulla or pons were associated with higher proportions of patients dead or in a vegetative state (P = 0.0156, OR 0.075). None of the 15 patients with brainstem lesions crossing the midline and a GCS motor score of ≤4 recovered. When MRI findings were coupled with GCS motor score, there was a strong correlation with poor outcome.

Lagares A Acta Neurochir 2009 Hospital 12 de Octubre, Madrid, Spain [33]	II (P)	2001-2004	100	GCS ≤12	Patients (age = 15-75) were prospectively enrolled in this study. Subjects with head injury had MRI (FLAIR, T2WI, T2*GRE) within 30 days (inter-quartile range 6-20 days) of trauma. Outcome was determined at 6 months using the GOSE instrument.	The investigators modeled their Diffuse Axonal Injury (DAI) Classification on the MRI after Adams et al. study [15]. Depth of lesion was classified into Grades 1-3. The depth of lesion was associated with poor outcome. <table><tr><th>Grade</th><th>Description</th><th>Patients</th></tr><tr><td>1</td><td>Subcortical White</td><td>65</td></tr><tr><td>2</td><td>Corpus Callosum</td><td>36</td></tr><tr><td>3</td><td>Brainstem</td><td>33</td></tr></table> Ninety-seven percent of patients with injuries to corpus callosum, and 94% of patients with TBSI also had injuries to subcortical white matter. In a multivariate logistic regression analysis model, Grade 3 DAI was significantly associated with unfavorable (GOSE) outcome (P <0.05). In addition, area under the curve (AUC) for receiver operating characteristics (ROC) assessing the role of MRI, GCS, and unfavorable outcome, there was a significant relationship when GCS motor subscore at admission was ≤4 [33] Figure 2 from Springer with permission). Mannion RJ J Neurotrauma 2007 Wolfson Brain Injury Unit, Cambridge, UK [25]	II (P)	2002-2005	46	GCS <8	This study aimed at finding the relationship between brainstem and supratentorial lesions in patients (mean age 34) with severe head injury and in need of ventilator support. The study was prospective, MRI field strength 3 Tesla, data acquisition within 3 days of trauma, and outcome evaluation at 6 months (GOS).	TBSIs were detected in 13 patients (28.2%). Computed tomography was positive for TBSI in only 2 (4.3%) patients. TBSI was in association with DAI in 6 patients, secondary to focal compression following herniation in 5 and with no evidence of supratentorial DAI in 2. Overall unfavorable outcome in this study was 61%. Eleven of 13 patients with TBSI (85%) had unfavorable outcome, including 5 who died (P <0.05). Outcome was favorable in 2 patients with TBSI and no evidence of global DAI. Poor outcome was more prevalent in TBSI associated with large supratentorial masses (5 patients) and diffuse injury (6 patients).												

Table 1. (Continued)

Study	Level	Years of Study	Patients	Level of Consciousness	Intervention	Outcome																																				
					Methodology required brainstem lesion on at least 2 MRI sequences (e.g., SWI and FLAIR).																																					
Woischneck D Childs Nerv Syst 2003 Otto von-Guericke University, Magdeburg, Germany [30]	III (R)	Not Mentioned	30	Severe GCS <8	Children <18 years of age who were comatose and needed respiratory support had MRI within a mean of 3.5 days (10 hours – 8 days) of trauma. T1 and T2 WI sequences were obtained. Field strength was 1.5 T. Subjects were followed from 3 months - 2.5 years to determine GOS outcome.	None of the 30 patients had evidence of TBSI on CT scan. TBSIs were noticed in 60% of children and were significantly associated with GOS score. BSI was secondary in 2 patients and primary in 16. Caudal pontine and medullary lesions were fatal.																																				
Firsching R Neurological Research 2002 Klinik für Neurochirurgie der Universität Leipzigstr, Magdeburg, Germany [36]	III (P)	Not Mentioned	102	Severe GCS <8	From 102 patients (mean age 36 years) 37 had mass lesions (11 EDH, 22 SDH, and 4 ICH). Twenty-four patients had decompressive craniectomy. Consecutive T1 and T2 MRI (field strength 1.5) study of patients was performed within 8 hours of injury. Neither SWI nor T2*GRE nor DWI was procured. - 3) Bilateral and posterior TBSIs at the level of the pons and mesencephalon are devastating and have unfavorable outcome [31, 34-36].
- 4) Addition of MRI variables to the core AUROC model and Rotterdam CT independent variables increases the discriminative power of prognostic models by improving the AUROC [33, 40].

In 2001, Firsching et al. from the Otto-von-Guericke University (Magdeburg, Germany) [36] prospectively investigated the prognostic value of TBSI seen on MRI in 102 patients (mean age: 36; range: 2-86) with severe TBI (GCS <8) who had MRI within 8 days of trauma. We downgraded this investigation to Level III because of minor weaknesses in the study design, precision, and methodology. MRI sequences were restricted to T1 and T2 WI, and there was no segregation of the TBSI into primary or secondary. Thirty-seven of 102 patients had surgery for a mass lesion including 24 who had decompressive craniectomy. Although the investigators precisely defined the location of the parenchymal lesions, no information was provided defining the lesion volume. The investigators classified TBSI into four grades Table 2:

TBSI was discovered in 58 patients. Patients with no evidence of TBSI had significantly less mortality ($P < 0.001$) than patients with TBSI, and bilateral pontine lesions were specifically catastrophic and 100% fatal ($P < 0.001$). In this study, with the exception of three patients, all patients with any evidence of TBSI also had supratentorial lesions. Patients with Grade I lesions had significantly better outcome than patients in Grade II and III categories. Good outcome was noted in 37% of Grade I patients in no Grade III patients.

Table 2. Grade of injury

Diagnostic groups of lesions based on MRI after severe head injury [36]			
Parenchymal Injury	Grade	Injury	No.
Supratentorial lesions only	Grade I	No TBSI	44
TBSI with or without supratentorial lesions	Grade II	Unilateral TBSI at any level	22
	Grade III	Bilateral midbrain TBSI	17
	Grade IV	Bilateral pontine TBSI	19

In a 3.5-year prospective MRI study of 30 children with severe head injury within 8 days of trauma, Woischneck et al. (Magdeburg, Germany, 2003) looked for evidence of TBSI [30]. It is likely that some of the investigated patients were among the 102 patients reported in 2001 by Firsching et al. Of note, the investigators took $P = 0.08$ as the level of statistical significance, and the minimum follow-up was 3 months using the GOS scale. None of the 30 patients had CT evidence of TBSI. Only two of 30 patients had secondary TBSI and 13 had primary. One hundred percent of patients with TBSI also had evidence of injury to supratentorial structures. Mortality in this series was 23%. Evidence of traumatic injury on MRI was seen primarily in the supratentorial structures in 12 patients (40%), and in 18 patients the brainstem was involved in addition to supratentorial structures. Death, persistent vegetative state, and severe disability were primarily concentrated in patients with TBSI.

Mannion et al. (2007, Cambridge), in a 37-month prospective study, investigated the relationship between TBSI and outcome in 46 patients who sustained severe head injury [25]. The investigators applied multiple MRI sequences using a 3 Tesla field-strength magnet,

acquired MRI within 3 days of trauma, and described the findings according to the Firsching Classification [36]. Thirteen of these patients (28.3%) had evidence of TBSI. TBSI in five patients was located dorsolateral to the mesencephalon most likely secondary to uncus herniation. In six patients BSI was “primary” and part of a more centripetal widespread diffuse axonal injury that involved subcortical white, central gray, and corpus callosum in addition to the brainstem. TBSI in two patients was isolated without DAI above the posterior fossa. Primary and secondary TBSI had an 85% chance of unfavorable outcome. Thirty-three of 46 patients had no evidence of TBSI with an unfavorable outcome of slightly more than 50% ($P = 0.05$). The results of this study indicated that a significant number of patients with severe TBI requiring ventilator support had brainstem injury that was not seen on CT. According to the authors, TBSIs in themselves were not predictive of outcome compared with TBSIs associated with more extensive DAI. Ommaya-Gennarelli’s hypothesis [6] of acceleration/deceleration/shear centripetal DAI therefore remains consistent with this study’s findings.

In a 5-year prospective prognostic study of 100 patients with moderate and severe TBI, Lagares et al. [33] classified MRI (median of 15 days following trauma) morphological pattern of injury (T2*GRE, T2WI, and FLAIR) based on Adams et al.’s centripetal distribution of histopathological findings. The cohort’s mean age was 33 and post-resuscitation GCS score in 63 patients was ≤ 7 Table 3.

Table 3. Patterns of rostral-caudal injury

Pattern I	Lesions confined to the subcortical white matter of frontal and temporal lobes
Pattern II	Lesions in subcortical white and corpus callosum
Pattern III	Lesions in dorsolateral mesencephalon and pons

Based on the Marshall et al. CT Classification, 72 patients in the Lagares et al. cohort had diffuse 1-3 injuries, 35 had mass lesions, but only four had evidence of brainstem damage. In this clinical investigation thirty patients had an unfavorable outcome, including five who died. MRI evidence of TBSI in 33 patients primarily involved the midbrain. There was a statistically significant relationship between unfavorable outcome and TBSI seen on MRI in this series. Based on the AUROC the prognostic model significantly improved when the core model GCS motor subscore was added to MRI covariates (Figure 2) [33].

In a 2011 study from Norway, Skandsen et al. assessed the predictive value of MRI on long-term outcome in 106 patients [38]. The cohort was a combined pediatric and adult (mean age: 28 years) and a mixture of moderately and severely disabled patients. From the 48 patients with severe head injury, 46% had TBSI. Bilateral TBSI was significantly associated with unfavorable outcome as measured by the Extended Glasgow Outcome Scale (GOSE) (Table 4).

In 2012, Chew et al. retrospectively analyzed a T2WI and T2*GRE volumetric analysis of TBSI in 36 patients [39]. Mean age was 45.5 years, and either subdural hematoma or epidural hematoma EDH was present in 21 patients. At 6-month follow-up 19 patients had poor outcome (17 died and two were in a persistent vegetative state). The mean volume of TBSI was 1.76 cm³ in patients who recovered and 6.13 cm³ in those who did not. TBSI involved midbrain in 22 (61%), pons in 17 (47%), and medulla in two (6%). The likelihood of TBSI crossing the midline increased as the lesion extended from the mesencephalon to the

medulla oblongata. T2WI sequence was a better indicator of volume of injury in TBSI. Stepwise logistic regression of all the variables indicated that lesions crossing the midline ($P = 0.0156$, $OR = 0.075$) and with a 24-hour motor score of ≤ 4 ($P = 0.045$, $OR = 2.25$) had the highest chance of poor outcome (C-statistic = 0.913).

Figure 2. AUROC indicating improvement in predictive significance of the prognostic model when motor sub-score and MRI variables are included in the statistical analysis. (From Lagares et al, Acta Neurochirurgica with permission).

Table 4. Prognostic factors and outcome in severe head injury, ordinal logistic regression

Depth	N	Good Recovery	Moderate Disability	Dead or Severe Disability	O R (95% CI) adjusted for age	P value
Hemisphere	12	8 (67)	4 (32)	0	Reference	-
Central Core	14	5 (38)	7 (56)	2 (14)	6.5 (2.2-38.7)	0.04
TBSI Unilateral	8	4 (50)	2 (25)	2 (25)	7.9 (1.0-62.4)	0.05
TBSI Bilateral	14	1 (7)	1 (7)	12 (86)	181.6 (16.5-2000)	<0.001

Hilario et al. [31] investigated the relationship between geographic location of TBSI on MRI (anterior, posterior, unilateral, bilateral, rostral, and caudal) and GOSE outcome in 108 patients (2012). Sixty-six percent of the patients had an unfavorable outcome. The investigators discovered that all patients with TBSI also had subcortical (47 of 51 patients, or 92%) or corpus callosal (36 of 51, or 71%) injuries. Eighty-four percent of patients had involvement of mesencephalon, 6% medulla oblongata and 4% pons. In 6% of patients TBSI involved multiple spots on the brainstem. The discriminatory strength of morphology of TBSI is indicated in the following Table 5.

AUROC = area under the receiver operating characteristics. CI = confidence interval. OR = odds ratio.

Table 5. Discriminatory strength of morphology of TBSI on outcome [Ref. 31]

MRI Findings	Good Outcome Present	Good Outcome Absent	P value	OR (95% CI)	AUROC
Nonhemorrhagic	58	19	<0.01	5.9 (1.6-22)	0.71
Unilateral	33	0	<0.05	-	0.69
Anterior	54	15	<0.05	6.8 (1.8-25)	0.72
Anterior+nonhemorrhagic	50	10	<0.01	9.5 (1.8-48)	0.82
Anterior+nonhemorrhagic+unilateral	60	8	<0.01	18 (3.5-93)	0.79

Figure 3. AUROC indicating progressive improvement in the discriminative power of the prognostic model when MRI values are added to the core and Rotterdam CT variables. (From Moen et al. with permission from J Neurotrauma [40]).

Moen et al. (2014, Norway) investigated the extent of diffuse axonal injury (volume and number of lesions) across the neuraxis on MRI and its effect on long-term functional outcome. In this prospective observational case control study, a cohort of moderate ($n = 64$) and severe ($n = 64$) patients had MRI within 8 days of trauma [40]. The subjects were followed for at least 12 months to determine their outcome on the GOS-E scale. The anatomical distribution of the amount (based on DWI) and volume (based on FLAIR) of DAI as seen on MRI following trauma was classified into three stages: Stage 1 - involvement of the hemispheres, Stage 2 - involvement of the corpus callosum, and Stage 3 - involvement of the brainstem. Nearly 30% of patients with severe TBI and 20% of patients with moderate

TBI had TBSI. The MRI covariates were included in a prognostic model that also included the core model and Rotterdam CT variables. Using this prognostic model, the AUROC had a much improved discriminating power in predicting outcome in comatose patients with TBSI (Figure 3) [40].

In a retrospective clinical investigation, Smitherman et al. [32] volumetrically analyzed FLAIR hyperintense lesions (FHL) in 63 children with moderate and severe head injury. This research project confirmed the rostral-caudal neuraxis dispersion of kinetic energy following trauma and validated the Ommaya-Gennarelli centripetal pathological distribution of lesions along the neuraxis. The investigators defined the Hyperintensity Lesion Volume Index (HLVI) as the FHL volume in one zone/whole brain volume $\times$ 100. Three zones were defined: Zone A was cortical, Zone B was central core (basal ganglia, thalamus, corpus callosum), and Zone C was brainstem. Ninety-three percent of patients in Zone C also had lesions in Zones A and B. In a logistic regression analysis, compared to patients with injuries in Zone A and Zone B, patients with lesions in all three zones had a significantly higher chance of unfavorable outcome (OR = 4.38 and 95% CI = 1.19-16). In addition, HLVI in Zone C by itself predicted poor outcome (Table 6).

Table 6. Functional outcome in different zones of injury (Ref. [32] Smitherman)

Pattern*	Number (%)	Favorable Number (%)	Unfavorable Number (%)
Zone A	19 (33)	16 (84)	3 (16)
Zones A+B	24 (42)	19 (79)	5 (21)
Zones A+B+C	14 (25)	7 (50)	7 (50)
Total	57	42 (74)	15 (26)

*In one patient FHLs were seen only in Zone C.

IMPLICATIONS OF THIS SYSTEMATIC REVIEW IN DECOMPRESSIVE CRANIECTOMY

We present an unpublished case report as a potential case for decompressive craniectomy (DC). A 26-year-old non-restrained female passenger was transferred to the Trauma Resuscitation Unit (TRU) at the University of Maryland R Adams Cowley Shock Trauma Center following a motor vehicle accident with a post-resuscitation GCS motor subscore of 4. Emergency Medical Technician records indicated respiratory arrest at the scene of accident. In the TRU she was already intubated when first evaluated by the neurosurgical service. The patient's GCS motor subscore was 4 and CT scan was consistent with DI2/DI3. Medical management was successful in maintaining acceptable intracranial pressure (ICP) and cerebral perfusion pressure (CPP) values (Figure 4) during her entire 7 days of hospitalization, after which time the family withdrew support. Admission CT scan (Figure 5, row A) of the head indicated minor intraventricular bleeding (arrow) and no significant finding at the level of the brainstem. FLAIR, SWI, and DWI sequences of her MRI on day 5 of admission was indicative of a centripetal injury to subcortical white, central core, corpus callosum, and brainstem (Rows B-D).

Figure 4. Post-resuscitation hourly ICP and CPP measures during the first 5 days of hospitalization indicating adequate medical management. (Courtesy of B Aarabi, University of Maryland).

Figure 5. Computed tomography (CT) of head at admission and magnetic resonance imaging (MRI) on day 5 of injury. Row A: Computed tomography views indicating evidence of intraventricular bleed (arrow). Row B: Fluid Attenuation Inversion Recovery (FLAIR) MRI views of brain indicating hyperintense subcortical, corpus callosum, central core and brainstem (mainly mesencephalon) injuries (arrows). Row C: Susceptibility Weighted Images (SWI) of brain indicating hemorrhagic subcortical, corpus callosum, central core, mesencephalon and pontine injuries. Row D: Diffusion weighted Images (DWI) views of brain indicating restricted diffusion in parasagittal and occipital cortices, central gray, corpus callosum and midbrain (arrows), (Courtesy of B Aarabi, University of Maryland).

Prior to the acquisition of an MRI study in this patient, and despite successful efforts to medically manage the patient's intracranial pressure, both the critical care and neurosurgery services braced for the possible need to carry out a decompressive craniectomy procedure for this patient. We know that intractable intracranial hypertension following trauma is deadly [49-53]; however, we also know that the majority of trauma patients respond to medical management [54]. Only 5% to 10% of patients with severe TBI need DC [24, 55-57]. For example, in the DECRA Trial, only 155 of 3478 (4.4%) patients, whereas in RESCUEicp, 206 of 2008 patients (10%) with severe head injury were eligible and enrolled in the randomized controlled trials [56, 57]. In one uncontrolled cohort study, only 50 of 967 (5.2%) patients needed DC for diffuse swelling [24]. In this case, the issue of possibly taking the patient to the operating room did not arise as the patient's ICP remained below the typically concerning threshold of 20-25 mm Hg throughout the hospitalization, with the exception of two temporary "spikes."

We argue that decompressive craniectomy would have led to unnecessary morbidity in this patient. Had the MRI study demonstrating the severity of this patient's injury not been acquired, and given that her diffuse injury was under-appreciated on her initial CT scan, we argue, she might very well have been taken for decompressive surgery in the event of a sustained ICP crisis. The MR images of this case clearly demonstrate the classic pattern of centripetally-directed injury as originally described by Ommaya and Gennarelli, proceeding from the subcortical white matter to the central core, corpus callosum, and brain stem. In the absence of the MRI study, the chances of devastating TBSI would have instead been reported for purposes of prognosis as anywhere from 25% to 50% [25, 31, 33, 34, 36, 39, 40, 58].

As presented in this review, the evidence provided from other groups and a case report from our own experience leads to the conclusion that the acquisition of FLAIR and possibly SWI MRI sequences may be useful before proceeding with decompressive craniectomy, in that it may foretell a grim prognosis and therefore prevent placing patients destined for a poor clinical outcome under unnecessary morbidity associated with the procedure. In other words, the families of patients with hyperintense or hemorrhagic TBSI lesions seen on MRI, in the setting of GCS motor subscore is ≤ 4 , should be counseled regarding future expectations and end-of-life decision making prior to undertaking this invasive surgical procedure.

Chapter 243

ROBOTIC PORTAL LUNG RESECTION

Roman V. Petro, Charles T. Bakhos and Abbas E. Abbas

Department of Thoracic Medicine and Surgery,
Lewis Katz School of Medicine at Temple University, Philadelphia, PA, US

INTRODUCTION

Alone or in combination with other modalities, surgical resection of lung cancer is the cornerstone of curative treatment for this devastating disease. This fact has remained true ever since the first oncologic lung resection, left pneumonectomy, was performed by Dr. Evarts Graham almost a century ago [1]. Resection of the cancer with an adequate margin along with the anatomical unit of lung in which reside lymphatics, vessels and parenchyma remains the gold standard of care, against which other ablative modalities must be judged. Whether this “anatomical unit” is a lobe, two lobes, one or more segments, or even a whole lung depends on both patient and tumor factors such as pulmonary functional status, comorbidities, location of tumor, size and histology. Increasing evidence is emerging of the oncologic equivalence of sublobar resection to lobectomy, especially for small or subsolid tumors [2, 3].

Safe surgical technique in the chest demands meticulous finesse in the hilar dissection of bronchovascular structures. This has traditionally required thoracotomy, a rib-spreading incision, big enough to accommodate surgeon’s hands to allow free bimanual dissection and assistance. This approach is still the most common access for lobectomy, as it provides excellent exposure of the hilum and pleural cavity. Unfortunately, this incision is also quite painful, and may be associated with higher morbidity, including chronic pain and impaired respiratory mechanics, leading to atelectasis and pneumonia. For this reason there has been a quest by thoracic surgeons to find a less invasive alternative.

Non-rib spreading video assisted thoracoscopic surgery (VATS) for lung resection has been the main approach for minimally invasive lung resection, providing better short-term outcomes in numerous studies [4-8]. However, VATS lobectomy is quite different from thoracotomy. The viewing angle is anterior, not superior, necessitating an anterior to posterior hilar dissection with division of the fissure last. With VATS approach posterior dissection, which is sometimes necessary, is quite difficult. The main VATS dissection technique is a

single rigid instrument, performing either a lift and burn or a push and spread of tissue instead of the time-honored surgical rules of bimanual traction and countertraction, with careful alternation of both blunt and sharp dissection. Despite these drawbacks, experienced surgeons have described use of VATS for advanced cases, including uniportal VATS sleeve lobectomies and pneumonectomies. However, VATS can only be safely recommended for small peripheral tumors that are not associated with significant hilar adenopathy [8].

As opposed to traditional VATS, robotic surgery allows the surgeon to manipulate the pulmonary hilar structures and mediastinal lymph nodes with excellent 3-dimensional visualization, facilitating the conduct of the operation. The wristed instruments allow unimpeded manipulation of the tissues and the ability to perform fine sharp dissection as we were taught in the open surgery, facilitating dissection of hilar structures and lymphadenectomy. In fact, robotic portal thoracoscopy has been likened to an open procedure done through the ports, or a “virtual thoracotomy” [9]. It gives the surgeon visual illusion of looking at the lung through an open chest and of being able to address the anatomy in a natural bimanual wristed technique.

By the early 2000’s, the first reports had appeared of *robotic-assisted thoracic surgery* (RATS) [10], described initially as an approach to patients with early-stage lung cancer. Since then, it has been consistently applied for more advanced cases such as segmentectomy, bilobectomy, pneumonectomy, sleeve resections and chest wall involvement (Figures 1-7), situations, where most VATS surgeons would otherwise opt (perhaps wisely) for thoracotomy [11].

Another important advantage of the robotic platform is the unique applicability to teaching and training. A double console (Figure 8) allows two surgeons to operate simultaneously and to switch control at any time. Attending surgeon with the use of telestration is able to direct trainee to perform increasingly complex tasks, while maintaining full visual control of the situation. In addition, surgical simulators have been developed that greatly enhance the ability of trainees to learn this new technology.

Figure 8. Teaching capabilities of double console.

COMPARISON OF ROBOTIC SURGERY WITH OTHER MODALITIES

No prospective randomized trials have compared the clinical outcomes of robotic surgery to other surgical approaches for lung cancer. However, numerous retrospective studies have reported on the benefits of robotic lung resection.

Although not the only criterion of the radicality of a cancer operation, studies have shown that the number of lymph nodes removed is equivalent in both robotic and open procedures [11]. In addition, studies have reported an upstaging frequency (i.e., ability to detect unexpected nodal metastasis) of 10-13% for robotic lobectomy which compares favorably with that of open lobectomy and is superior to VATS [12, 13].

When comparing to open thoracotomy, one study of a cohort of 168 patients showed that those, undergoing robotic lobectomy, suffered less perioperative morbidity (27% vs. 38%), had shorter chest tube drainage (1.5 vs. 3 days) and required shorter hospital stay (2 vs. 4 days) [11]. Another study showed less postoperative pain and shorter hospital stay in patients who underwent robotic compared to open lobectomy [14].

Studies have also compared RATS to VATS lung resection. One retrospective case-control analysis, comparing RATS with VATS in two matched groups, found that RATS patients received less narcotic analgesia and resumed their normal activities sooner [15]. As part of a large database study of 33,095 cases of lobectomy and segmentectomy between 2008 and 2010, RATS, when compared to VATS, was associated with lesser mortality (0.2% vs. 1.1%), shorter hospital stays (5.9 days vs. 6.3 days), and lower complication rates (43.8% vs. 45.3%), although these differences did not reach statistical significance [16].

Far fewer studies have reported on the long-term survival after robotic lobectomy for lung cancer. One of these is a retrospective study of stage-specific survival for 325 consecutive patients, who underwent robotic lobectomy for NSCLC at three centers (two in Italy, one in the USA) over an 8-year period from 2002 to 2010. Median follow-up was 27

months and overall 5-year survival were 80%: 91% for stage IA, 88% for stage IB, and 49% for stage II. Three-year survival for stage IIIA patients was 43%. These results are at least equivalent for those expected after VATS or thoracotomy [13].

Table 1. Robotic preprocedural emergency conversion timeout drill

Role	What to do
Anesthesiologist	Call for additional anesthesia support Avoid inflation of the lung
Circulating Nurse	If thoracotomy instruments not already open do that first. Call for additional help Deliver blood to anesthesia team Notify blood bank to prepare for more units
Scrub nurse or technician	Leave gown and glove on side of cart for surgeon to self-gown Do not remove or switch off camera Undock only the arms that the console surgeon specifies. Have thoracotomy instruments open Have bedside instrument-release wrench available
Bedside surgeon	Depends on the situation: If holding pressure on a bleeding vessel then continue to do that and do not assist in the undocking process If control is lost then make an emergent thoracotomy (at 5 th intercostal space)
Console surgeon	Scrub, gown and glove oneself Call a colleague to assist Keep calm and carry on

Despite these potential benefits of robotic surgery some valid concerns still exist. A frequent criticism of RATS is limitations in the event of uncontrollable hemorrhage. The primary surgeon is not even at the bedside, is not sterile, and there is a heavy machine on top of the patient. Converting the case to open thoracotomy necessitates removing the instruments and ports, undocking the robot, sterilely scrubbing the surgeon and rapidly gaining an open access to the chest. This exercise can be accomplished in seconds if the team is familiar with the logistics of this critical process. For these purposes it is important to frequently review this emergency scenario as a drill with the entire surgical team so when the crisis strikes, each individual in the room knows exactly what his or her role is. These authors routinely announce a preprocedural “timeout,” reviewing the role of each person in the room; the anesthesiologist to call for assistance, the circulating nurse to call for blood, the scrub nurse to start the undocking procedure and the assistant to perform whatever is necessary at the time (e.g., holding pressure on a bleeding vessel or making a thoracotomy; Table 1). VATS and thoracotomy instruments should be immediately available. Although the need for conversion will diminish with experience, bleeding emergency should be an expectation not a surprise in any busy thoracic program, especially as surgeons undertake increasingly complex cases [9].

Perhaps the biggest drawback of robotic surgery is the hefty price tag, which makes it not affordable to the vast majority of surgeons and their patients in the world. In the future this price will likely to diminish as we see more competition amongst manufacturers and academic institutions. Furthermore, robotic surgery may actually be more profitable when it leads to better outcomes, shorter hospital stays and faster returns to work. It should therefore be preferentially selected for cases with high acuity such as thoracic procedures where these

benefits will make the most difference. Using it for simple outpatient procedures on the other hand may not be cost-effective at present [17].

TECHNIQUE

We have previously described our technique for robotic lobectomy using da Vinci Xi Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) and a four-arm, totally portal approach [18]. We do not employ a utility incision and all assistance is accomplished through the assistant port. Extraction of the specimen is done trans-diaphragmatically through a subcostal incision rather than the more common approach of intercostal extraction employed by other surgeons. It is the authors' opinion that this is the only really portal based procedure since removing a large specimen through an intercostal space will inevitably cause a degree of rib-spreading.

After induction of general anesthesia, lung isolation is achieved by either a bronchial blocker or a double lumen tube. We prefer the bronchial blocker for several reasons. First, its smaller profile allows safer and easier dissection around the airway. Second, larger inner diameter of the single lumen endotracheal tube allows toilet bronchoscopy at the end of the procedure by simply removing the blocker. Finally, if the patient cannot be extubated immediately after completion of the procedure, it obviates the need for a potentially dangerous exchange of the double lumen tube. Next, the patient is moved into the lateral decubitus position, and the bed is flexed to 150 degrees at the level of the 8th intercostal space (ICS). The robot is positioned behind the patient's head.

Five ports are then inserted (Figure 9). Care is taken to position these ports approximately 10 cm apart (about a hand's breadth) in order to avoid external collisions between the arms. We attempt to place all 4 ports in the 8th intercostal space. The first port of entry is at the posterior axillary line (PAL). We then place a camera endoscope, start carbon dioxide insufflation at a pressure of 10 mm Hg and confirm the placement of the other ports. Three other robotic ports are placed in the 8th intercostal space at the midclavicular line (MCL) (12mm), anterior axillary line (AAL) (8mm) and paraspinal line (PSL) (8mm). We ensure that this last posterior port is at least 5 cm from the lateral border of the spine in order to avoid injury of the intercostal bundle in the narrow posterior aspect of the intercostal space. These ports are placed in the same locations for both left and right sided procedures. An assistant port (15mm) is then placed subcostally near the tip of the 11th rib and through the insertion of the diaphragm. Using this technique, our port locations have been the same for all past and current da Vinci robot models. The robot is then docked from the head of the table, and the surgeon takes position at the console. Camera is placed in the anterior axillary line port and working instruments include Bipolar Maryland Forceps in the most medial port, Cadieere Forceps or Fenestrated Bipolar Forceps in posterior axillary line port and Tip Up Fenestrated Grasper or Double Fenestrated Grasper in the most posterior port.

After initial inspection to rule out pleural metastatic disease, we begin by mobilizing the hilum. For dissection and tissue division we prefer bipolar energy technique. The other surgeons hand assist in manipulating the lung, providing exposure. Arm in the paraspinal port serves as a static retractor. Bedside assistant, utilizing 15 mm subcostal port, passes gauze

rolls, vessel loops, retrieves specimens, provides suction for clearance of the blood and operates endostaplers if robotic stapling is unavailable.

Figure 9. Diagram of robotic ports location.

Figure 10. Completion of the robotic lung surgery. Note same interspace location of ports and subcostal location of the extraction incision.

Initially, the inferior pulmonary ligament is divided followed by the mediastinal pleura circumferentially around the hilum. In the process, the mediastinal lymph node dissection is completed before division of any bronchovascular structures and all nodes are removed in a protective bag to avoid spillage. Completing the nodal dissection first facilitates the exposure of the hilar structures and allows frozen section exam of any suspicious findings.

Following this, the lobar vein, artery and bronchus are divided according to the individual patient anatomy and surgeon preference as opposed to VATS where anterior to posterior approach (vein to artery to bronchus) is almost mandatory. The vascular structures are divided with the robotic 30mm curved vascular load, while the green load is used for the bronchus (30 mm) and parenchyma (45 mm). At the end, the specimen is placed in the retrieval bag and the

robot is undocked. The assistant port incision is then extended to about 3-4cm and the specimen is removed. A chest tube is placed through the anterior port site followed by closure of the incisions in the standard fashion (Figure 10). Care is taken to use permanent suture for reinsertion of the edge of the diaphragm to the 10th rib.

Bimanual wristed motion of the robotic instruments provides unique opportunity for finesse tissue management, allowing advanced minimally invasive resection in complex locally advanced situations or sublobar resections. For sleeve bronchial resection, once bronchus is divided, continuous absorbable 3-0 V-loc suture (Medtronic, Minneapolis, MN)) is used for bronchial anastomosis. In cases of pulmonary artery sleeve resection proximal and distal vascular control is achieved by application of laparoscopic bulldog clamps. We prefer 25 mm curved bulldog clamps.

In cases of chest wall invasion, attachment of the lung to the chest wall frequently provides excellent retraction for hilar dissection and whenever possible we approach the hilum first. However, when visualization is impaired by the fixed lung, resection of chest wall can be accomplished as an initial step. At least two to three-centimeter resection margin is required in these cases. Hot Shears is an excellent instrument for the dissection and division of the intercostal muscles. Whenever angle is appropriate, we use Dennis Rib Cutter (Figure 3; Scanlan International, Saint Paul, MN), advanced through the assistant incision after removal of the port for rib resection. When invasion is in the apical aspect of the chest, with limited reach of the Rib Cutter, a fragment of Gigli saw is passed around the rib and is used to divide the bone with both robotic arms. Finally, in difficult angles when none of these techniques work, Gigli saw can be brought outside with Carter-Thomason (CooperSurgical, Inc., Trumbull, CT) device through two stab skin incisions around the rib and can be used externally by bedside assistant for rib division.

FUTURE DIRECTIONS

Robotic technology continues to evolve with new and exciting advances on the horizon. One of these promising approaches is a navigational technology, i.e., the ability to direct the surgeon to a target that is too small or deep to localize. A recent publication by this author's group describes electromagnetic navigational bronchoscopic localization of small, deep or subsolid nodules and injecting them with Indocyanine Green (ICG). Using near infrared laser emission by specially equipped robotic cameras allows easy identification of the autofluorescent nodules [19]. Further developments may allow navigational technology to direct the robot itself to the target nodule. Yet another important area of innovation in robotics is virtual haptic feedback, which would allow the surgeon to palpate and feel the consistency of tissue. Additional potentially revolutionary innovation would be the ability to intermittently overlay a reconstructed 3-dimensional study (e.g., CT scan or MRI) over the real time video image. This would enable the surgeon to more easily identify hidden structures such as the pulmonary vessels or difficult nodules.

INTRODUCTION

The Robotic-assisted technique for resection of mediastinal masses has been adopted for almost two decades. From its initial adoption, case reports, series, and retrospective studies demonstrated the safety and efficacy of this approach. More importantly, they demonstrated the ability to replicate an open procedure through minimal access incisions [1-3]. This chapter focuses on the indication for robotic assisted resection of mediastinal masses, preoperative work-up, operative technique, and the advantages of utilizing the robotic approach.

INDICATION FOR ROBOTIC-ASSISTED MEDIASTINAL MASS RESECTION

We do not alter our work up or management based on our preferred surgical approach when evaluating mediastinal masses for resection. The same guidelines applied for open surgical resection should also be followed when considering a robotic approach. In general, a resectable thymic mass, teratoma, residual germ cell tumor despite adjuvant therapy, neurogenic tumors, and symptomatic bronchogenic or pericardial cysts are all common indications for surgical resection. Regardless of the type of tumor, a thorough work up of the mediastinal mass is performed prior to surgical management in order to achieve good outcomes. This includes a multidisciplinary team approach, the consideration for a preoperative biopsy, or potential neoadjuvant therapy when indicated. We favor imaging with a contrast CT and/or MRI of the chest to evaluate the vascular anatomy and the extent of structural invasion if present. Pulmonary Function Testing (PFTs) is also checked.

ROBOTIC CREDENTIALING AND ACCREDITATION

Prior to embracing robotic assisted surgery for mediastinal mass resection, we recommend that the thoracic surgeon achieves the appropriate level of competency as outlined in his or her institutional credentialing bylaws. A combination of an online practical introduction, a cadaveric workshop, case observations, and performing the first few cases with proctor supervision is recommended prior to independent utilization of the system. In our experience, this stepwise fashion aids to cultivate the required skills allowing the surgeon to adapt to the 3-dimensional (3D) vision thus compensating for the lack of haptic feedback on the robotic platform [4].

OPERATIVE TECHNIQUE

A. Anesthesia:

General anesthesia with double lumen intubation or a bronchial blocker. An arterial line is placed for continuous blood pressure monitoring.

B. Positioning:

For anterior mediastinal tumors, the patient is placed in a partial lateral decubitus position. The right chest is our preferred site of surgery. However, if the dominant portion of the mass is on the left side, we approach it from the left. For posterior and middle mediastinum, full lateral decubitus position is preferred. The table is flexed right above the level of the hip, and a reverse Trendelenburg position is obtained to level the thoracic cavity. The ipsilateral arm is rotated anteromedially and supported with an arm stand as shown in Figure 1.

Figure 1. Positioning: Patient in in partial right lateral decubitus in a left sided approach with left arm supported with an arm stand. Port positioning is as shown for both Xi and Si.

Figure 2. The robot is placed to the patient's right. And docked straight in with an Si or an Xi.

A. Port placement: (Both Xi and Si)

We utilize 3 robotic ports (8mm) and 1 assistant port (12mm), for retraction and passing sponges if needed. We start by entering the chest under thoracoscopic or direct vision for safe entry at the level of the 6th intercostal space, mid-axillary line.

1. We recommend the use of local anesthesia and a multilevel intercostal block during the process of port placement or at the completion of the procedure to assist in postoperative pain control.
2. Camera port: The 6th intercostal space mid-axillary line entry site is used as the camera port. Usually this is 8mm or 12mm in size for the Xi or Si respectively.
3. The remaining two robotic 8mm ports are placed 5 fingerbreadths away from the camera port; one to its left, and another to its right.
4. The left 8mm port is placed in the 3rd intercostal space at the level of the mid-posterior axillary line to prevent the need for acute angulation of the wrists of the instrument while dissecting deep in the mediastinum. In such circumstances, the wrist can rub on the chest wall and/or internal thoracic vessels.
5. The right 8mm port is placed in the 5th intercostal space, anterior-midaxillary line.
6. An assistant port is then placed under direct vision in the same rib space or one space lower than the inferior robotic arm, along the mid clavicular line or a fire centimeters lateral to it. The robot is docked from the patient's right side as shown in figure 2. We tend to use the assistant port as an accessory robotic arm to make use of the added benefit of having a grasper in one hand, a dissector in another hand, and the vessel sealer in the third hand. This allows for a totally robotic procedure and helps significantly in maintaining precise retraction and exposure.

B. Essential Instruments:

1. Fenestrated bipolar
2. Robotic sealer (The vessel sealer has an excellent geometrical shape with smooth edges making it ideal for blunt dissection around the innominate vein and other delicate areas)
3. Long tip bipolar dissector

C. Intrathoracic Steps:

1. CO2 insufflation is used to assist in exposure and dissection.
2. No touch technique.(Avoid touching the actual tumor)
3. Circumferential dissection with acceptable margins is performed starting inferiorly and working our way up seperiorly.
4. Critical structures are identified and protected. This may include the phrenic nerve, the SVC, and the recurrent laryngeal nerve. It is important to remain cognizant of the robotic instruments' wrists while operating to avoid accidental traction or injury to these critical structures. Depending on the extent of resection, one may need to identify the contralateral phrenic nerve. In such cases, utilizing a 30 degrees scope might be helpful.
5. Hemostasis is achieved by using bipolar dissection. Larger vessels are divided with the vessel sealer.
6. The specimen is retrieved in a sterile bag through the assistant's port.
7. A channel drain is placed through lowest port and placed across the mediastinum
8. The chest tube is removed and the patient is discharge on postoperative day 1.

DISCUSSION

We believe that the robotic platform is ideal for access and resection of mediastinal masses. It provides excellent exposure and easy maneuverability in this tight area. We do acknowledge that a median sternotomy is still preferred by some surgeons for resection of larger anterior mediastinal masses. This is mainly due to the excellent exposure it provides to the mediastinum and the ability to extend the incision to a hemi- or full clamshell for more exposure when needed [5]. However, the robotic 3D camera provides excellent visibility and exposure. Recent data supports robotic assisted resection of large mediastinal tumors up to 12.5cm in size [6]. Therefore, we do not feel that the large tumor size per se warrants an open approach. We use our judgment based on the level of invasion to surrounding structures if present, and on the consideration of a potential need for mediastinal node assessment as is the case in staging for thymus malignancy [7]. In the latter situation, we feel that a robotic technique is favorable since the aortopulmonary window and paratracheal lymph nodes are difficult to reach via sternotomy. The primary goal when approaching mediastinal tumors should be the ability to safely achieve negative margins. The advantage of the robotic platform in this regard includes the wrist movements feature, targeted precision and the

elimination of operator's tremor, reproducibility of the procedure, and the enhanced 3D camera visibility. These added benefits, as opposed to the 2D camera and the lack of articulating instruments with VATS, provide the robotic approach with the capability to replicate the steps of an open sternotomy approach, but of course with smaller incisions.

There are no randomized controlled trials to date comparing the robotic approach to the gold standard open approach. However, retrospective data demonstrate feasibility in terms of safety, achieving negative margins, decreasing the hospital length of stay, and providing an acceptable rate of complications. Radkani et al. reported their results on 49 patients who underwent robotic mediastinal mass resection over a 4-year period. Their study demonstrated the ability to access tumors in various locations of the mediastinum [6]. Moreover, a propensity-matched analysis comparing 100 patients in each group who underwent robotic or trans-sternal thymectomy demonstrated comparable long term outcomes. Based on these results, the authors concluded that robotic thymectomy should be considered an alternative surgical option for treating anterior mediastinal masses [8]. In addition, a study by Raad et al showed that robotic access is associated with lower narcotic requirements when compared to sternotomy [9]. Finally, a propensity-matched analysis by Seong et al comparing 37 robotic to 145 open resections demonstrated lesser tube drainage, lower blood loss, shorter tube days and length of hospital stay without any postoperative complications in the robotic group [10].

In conclusion, Robotic-assisted mediastinal mass resection is a feasible, safe, and reproducible approach. It should be attempted as the first line approach for mediastinal mass resections. A gradual and systematic methodology for credentialing and accreditation on the robotic platform is advised prior to embracing this advanced operative technique.

Chapter 245

ROBOTIC ASSISTED MINIMALLY INVASIVE ESOPHAGECTOMY FOR ESOPHAGEAL CANCER

***Matthew C. Black, MD, James D. Luketich*, MD
and Inderpal S. Sarkaria†, MD***

Department of Cardiothoracic Surgery, The University of Pittsburgh School of Medicine
and the University of Pittsburgh Medical Center, Pittsburgh, PA, US

INTRODUCTION

Esophageal cancer remains a prevalent problem both worldwide and in the United States. It is the eighth most common malignancy across the globe with nearly half a million people affected, the majority of which are in Southeast Asia [1]. In the United States, the estimated incidence in 2017 is 16,940. Of these, nearly 15,690 people will succumb to this disease. Despite these daunting statistics, the outcomes for esophageal cancer are steadily improving. In the 1950s, 5-year survival rates were around 4%, compared to 9% in the late 1980s [2]. Today, survival rates have doubled to 18% [3]. The improvements can be attributed to advances in multimodal therapy as well as refinements in surgical technique.

While the best approach to surgical resection remains controversial, a number of techniques have been described, with variations on these methods being developed as technology has advanced. Prior to laparoscopy, three main approaches had been utilized [4]. The choice of operation was based on tumor location and/or surgeon preference. The location and histology have seen a shift in recent decades in Western nations, with increased prevalence of adenocarcinoma of the gastroesophageal junction and lower third of the esophagus over squamous cell carcinoma of the mid and upper esophagus [5]. The traditional operative approaches to these malignancies include transhiatal (laparotomy with cervical neck anastomosis), Ivor-Lewis (laparotomy and thoracotomy with thoracic anastomosis) and McKeown, or three-hole, approach (thoracotomy and laparotomy with cervical neck anastomosis) [4]. As thoracic surgeons have become more facile with laparoscopy and

* Henry T. Bahnson Professor and Chair, Department of Cardiothoracic Surgery.

† Vice Chair, Clinical Affairs & Director, Robotic Thoracic Surgery.

thoracoscopy, minimally invasive esophagectomy (MIE), in various forms, has developed and gained a significant degree of prominence worldwide. Similarly, with the introduction of advanced robotic minimally invasive technologies over recent decades, robotic assisted minimally invasive esophagectomy (RAMIE) has also developed as an alternative approach to standard laparoscopic and thoracoscopic MIE.

The indications for resection of esophageal cancer by RAMIE are essentially the same for MIE. Endoscopic biopsy establishes the pathologic diagnosis of esophageal cancer as well as delineates the extent of proximal and distal disease. The depth of intraluminal invasion or local spread to lymph nodes is determined by endoscopic ultrasound (EUS). A staging CT scan of the chest, abdomen, and pelvis is utilized, often with fluorodeoxyglucose-18 positron emission tomography as an adjunct, to evaluate the primary tumor and identify metastatic sites of disease, as well as monitor response to induction therapies [6]. Bronchoscopy is utilized for assessment of invasive airway involvement, in particular with middle and upper esophageal tumors. Staging laparoscopy may allow for assessment of bulky gastric tumors and adenopathy, and occult intraperitoneal metastases [7]. Patients with T3 (or greater) disease or those with suspected or confirmed lymph node involvement (N1 disease) by EUS are referred for neoadjuvant chemotherapy or chemoradiation followed by surgical resection. Those with T1-2 disease are considered for upfront surgical resection [4]. Patients considered unfit for surgical resection are referred for definitive chemoradiation.

Robotic technology builds on the advantages of standard minimally invasive surgery. These added benefits include magnified stereoscopic and central optics, articulation of instrument arms with superior freedom of motion, an additional surgeon arm to allow self-assistance, and direct control of all these components under the primary surgeon, in comparison to standard laparoscopic/thoracoscopic approaches [8]. Similar to MIE, reports of RAMIE have demonstrated oncologic outcomes similar to MIE and open operations, without compromising patient safety. Given the highly complex technical aspects of an MIE, the technology of robotic surgery may demonstrate a facilitated learning curve as systematic approaches are developed [9, 10]. At this time, RAMIE, when performed in high volume centers, demonstrates equipoise compared to standard MIE as a viable option for the surgical treatment of esophageal cancer [8, 11].

HISTORY AND DEVELOPMENT

Similar to the development of other robotic surgical approaches, the RAMIE lagged behind the laparoscopic MIE by about a decade. Horgan et al. described the first robotic esophagectomy as a transhiatal approach in 2003, utilizing a gastric conduit with a cervical incision and neck anastomosis [12]. Kernstine et al. published the first series of robotic transthoracic esophagectomy via a McKeown approach. This series consisted of 14 patients, with progression throughout the series from a hybrid (robotic assisted thoracoscopic with laparoscopic abdomen) approach to the last eight being completely robotic chest and abdominal operations [13]. This series demonstrated initial feasibility of transthoracic robotic esophagectomy.

APPROACH

Most initial reports included a three-hole approach with variation among how the abdominal dissection was completed. While Kernstine et al. shifted toward both a robotic transthoracic and abdominal approach, Boone et al. published a series of 47 patients with a robotic chest portion, but still utilized laparotomy or laparoscopy to complete the gastric and transhiatal dissection [14]. Putambeker et al. described the transthoracic three-hole approach in a series of patients that were placed in the prone position to perform the thoracic esophageal dissection. The setup included a 12 mm port placed just off the inferior border of the scapula in the 5th or 6th interspace, two 8 mm ports placed 5 cm apart in the 3rd and 8th interspace, and a fourth 10 mm assistant port placed between the left arm and the camera port. The authors felt the prone positioning allowed the esophagus to fall anteriorly, providing tension and simplifying the dissection, which was started just inferiorly to the azygous vein. The anterior three-fourths dissection was completed and then the aortic plane was dissected last. Complete thoracic dissection was carried caudally to the hiatus to above the azygous vein, keeping it preserved [15].

Dunn et al. expounded on the initial approach described by Horgan. This approach mimics the open transhiatal approach utilizing a robotic abdominal portion to perform the paraesophageal dissection with an open cervical incision and anastomosis. A camera port is placed to the left of the umbilicus. The two robotic working ports are then placed 8 cm to both sides of this port and 4 cm above. Additional ports are placed for the liver retractor and an assistant port. In this series, the intraabdominal portion is completed laparoscopically including mobilization of the stomach, dissection of the hiatus, dividing the short gastrics, mobilizing the duodenum, and dividing the left gastric as well as the lymphadenectomy. The robotic dock is then brought into place and the mediastinal lymphadenectomy and esophageal mobilization was then completed. The robot was then undocked and the gastric conduit was created, followed by cervical dissection and anastomosis in the standard fashion [16].

Sarkaria et al. described the first total robotic Ivor Lewis approach, initially in 21 patients, and in a subsequent report including 100 patients from Memorial Sloan Kettering Cancer Center [10, 17, 18]. The initial experience was performed using the Da Vinci Si (Intuitive Surgical Inc, Sunnyvale, CA), with a more recent transition to the Da Vinci Xi platform. The newer platform allows refinements in ease of positioning and technique, but the essentials of the operation are unchanged [19]. For the abdominal portion, the patient is placed in the supine position on the right edge of the operating room table to maximize utility of the liver retractor. The right arm is abducted 45° and the left arm may be tucked to the patient's side or left out. A footboard allows placement in steep reverse Trendelenburg position. For the thoracic portion, the patient is placed in standard left lateral decubitus position on a bean-bag with the left arm slight flexed on an armboard and the right arm suspended. Slight modification to a lower and more cranial position of this arm may facilitate working in the axillae (Figure 1) [19].

The abdominal approach utilizes a 12 mm Hasson cutdown port which will be used for a 10mm, 30-degree camera. The remaining ports placed under direct visualization include left sided 5 mm subcostal and 8 mm midclavicular ports, a 5 mm right subcostal port used for a liver retractor and an 8 mm right subcostal working port. A 12 mm assistant port is placed periumbilical. For the thoracic portion, a Veress needle is utilized to gain access to the chest

with insufflation of gas. A 12 mm port is placed in the 8th interspace in the mid axillary line. Additional 5 mm and 8 mm ports are placed in the 3rd and 5th interspace of the anterior axillary line, respectively. An 8 mm working port is placed in the 9th interspace off of the scapular tip. A 12 mm assistant port is placed between the camera port and the left 8 mm working port in the 10th interspace (Figure 2) [19]. Standard instrument setup includes a fenestrated bipolar in the robotic left hand and robotic ultrasonic shears in the right hand. The fourth arm is utilized as a retracting arm usually with a Shertl atraumatic grasper. The dissection in both the abdomen and chest mimics the MIE dissection as developed and described at the University of Pittsburgh, including lymphadenectomy, creation of gastric conduit and esophageal mobilization [20]. Okusanya et al. described the first early series of RAMIE at the University of Pittsburgh, which identified excellent perioperative outcomes similar to the institution's extensive MIE experience, and with a higher median number of lymph nodes harvested [8, 21].

Figure 1. Robotic-assisted minimally invasive esophagectomy (RAMIE) operating room setup for the abdominal (A) and thoracic (B) phases. (Courtesy of Memorial Sloan-Kettering Cancer Center, New York, NT; with permission).

As an adjunct to our operative technique, we have instituted using near infrared imaging (NIFI) for confirmation of critical vascular structures and conduit perfusion assessment. In a prospective observation trial, thirty patients were assessed by a single dose indocyanine green (ICG) injection prior to conduit creation during RAMIE. The median time to fluorescence was only 37.5 seconds and identification was successful in all cases. Given that this technology is already available in the robotic platform and a short duration to fluorescence there is little downside to performing a confirmatory test to provide safe mobilization of the gastric conduit as well as determine the terminus of the right gastroepiploic arcade [22].

Figure 2. RAMIE port placement for the abdominal (A) and thoracic (B) phases (Courtesy of Memorial Sloan-Kettering Cancer Center, New York, NT; with permission).

ANASTOMOSIS

The techniques utilized for esophageal anastomoses are based upon techniques demonstrated with open techniques. The initial series with robotic three-hole esophagectomy and robotic transhiatal approaches both utilized open cervical incisions [14, 15]. For this reason, they will not be covered in detail.

Similar to the initial hesitancy for a thoracic anastomosis in MIE, the same concerns exist when considering an Ivor-Lewis RAMIE. Hess et al. describe an EEA stapled anastomosis similar to that described by Luketich et al. with non-robotic MIE [20]. The esophageal anastomosis is created using a stapled end to side technique with our preference being a 28 mm EEA stapler. However, if the esophagus is small, a 25 mm EEA stapler has been used on occasion. To accommodate specimen removal and introduction of the EEA stapler, an access incision is created below the posterior 8 mm port and extends 4 cm in length. The anvil is inserted and placed in the open end of the esophagus after placement of a running “baseball stitch” suture. The suture is then snugged and secured and a second superficial pursestring suture reinforces the anvil. Anvil insertion is performed using Cadiere forceps given the stronger grip strength compared to the fenestrated bipolar forceps. A gastrotomy is made in the proximal conduit to accommodate the stapler, with the gastrotomy to be closed after completion of the EEA anastomosis [8]. The docking of the spike into the anvil and stapler deployment is similar to open or minimally invasive techniques [19].

Leak rates using this method have been reported in the 4%-7% range and are similar to those reported for MIE [8, 10, 18, 20].

Hodari et al, described a hybrid stapled and sewn technique in a cohort of 54 patients published in 2015 [23]. The posterior layer was completed with a linear stapler after the esophagus and conduit were oriented similarly to that described by Orringer [24]. The anterior layer was completed in a 2-layer sewn anastomosis. Three patients (5.4%) experienced anastomotic leaks. This series utilized indocyanine green and near infrared imaging to assess conduit perfusion at the time of anastomotic completion [23].

Cerfolio et al. described their early progression from a stapled to a fully hand-sewn robotic anastomosis [25]. In this series of 22 patients, the first six were performed by a hybrid stapled and sewn anastomosis, as described above. However, this was abandoned due to five major conduit/anastomotic morbidities early in this experience. A 2-layer completely sewn anastomosis was adopted, despite the increase in operative time. The posterior layer is composed of interrupted silk suture approximating the posterior muscular layer of the esophagus to the serosa of the stomach. A running PDS suture constructs the inner layer and the anterior layer is completed in a series of Lembert sutures with the knots secured extraluminally. With this technique, the authors reported no major anastomotic related morbidities in the last 16 patients of the cohort.

NODAL DISSECTION

A thorough examination of an adequate number of lymph nodes provides for accurate staging, prognostic data, and potentially improved survival [26, 27].

The initial robotic experience has demonstrated equipoise in performing an adequate lymph node dissection. In the 2 largest series utilizing the three-hole technique, Boone et al had a median of 29 lymph nodes, while Putambekar et al. harvested 18 [14, 28]. Weksler et al. compared 11 patients undergoing RAMIE to 26 patients undergoing MIE within a single institution and there was no difference between lymph node yield, 19 vs 20.5, respectively [29]. Using a transhiatal approach, Dunn et al. reported a median of 20 lymph nodes obtained but only a median of 4 within the mediastinum ranging from 0-12 [16]. Coker et al. obtained a median of 15 lymph nodes (range, 5-29) [30]. The Ivor-Lewis RAMIE demonstrated consistent median lymph node harvests between 18-26 lymph nodes at their respective institutions [8, 18, 25, 31].

ONCOLOGIC OUTCOMES

In Boone's series of 47 patients undergoing a three-hole esophagectomy, R0 resection was achieved in 76.6% of patients, and Putambekar reported a 97.6% rate [14, 28]. The transhiatal approach was able to obtain a 94% rate of R0 resection despite no transthoracic dissection [16]. The Ivor-Lewis RAMIE approach also provides adequate resection, with rates of complete resection reported from 90%-100%, similar to those reported for MIE [8, 10, 18, 20, 23].

Little 5-year oncologic data had been published regarding RAMIE being a viable oncologic operation to rival an open esophagectomy or MIE. Van der Sluis et al published a series of 108 patients, followed for at least 29 months and with some up to 5 years. This

cohort underwent a thoraco-laparoscopic RAMIE (prone chest) with a two-field lymphadenectomy and cervical anastomosis (ROBOT trial). Most patients were clinically stage T3 or higher (78%) with and over two-thirds had clinical lymph node involvement (68%). The patient cohort mirrored the shift to patients predominantly presenting with adenocarcinomas (78%). In 65% of the patients, neoadjuvant therapy was administered and an R0 resection was achieved in 95% [32].

Median follow up was 58 months with none lost to follow up. The 5-year survival for this cohort was 42%. Consistent with previously published data, ten patients (14%) had a pathologic complete response [33]. Median disease free survival was 21 months. In patients with recurrent disease, only 6% had isolated locoregional disease, demonstrating a viable oncologic operation. Recurrence rates in this series were also consistent with published data on recurrent disease after open esophagectomy [34].

SAFETY

In high volume centers, operative mortality for RAMIE is low, similar to trends seen with open esophagectomy [11, 18]. Mortality in Boone et al.'s cohort of three-hole esophagectomy was 6.3% with three in-hospital deaths, while Putambekar et al. reported no 30-day operative mortality [14, 28]. Dunn et al.'s cohort of transhiatal robotic esophagectomies reported a mortality rate of 2.5% [16]. With experience and a dedicated team approach specific to the RAMIE Ivor Lewis operation, Sarkaria et al. and Okusanya et al. have reported 90-day mortality rates of 1% and 0%, from MSKCC and UPMC respectively [8, 10].

Pulmonary complications, including pneumonia and respiratory failure, remain a major cause of morbidity with esophagectomy. While data specifically regarding RAMIE is accruing, standard MIE has shown a significant decrease in pulmonary related morbidity compared to open procedures in a randomized controlled study [35]. Importantly, with both RAMIE and MIE, specific care must be taken to avoid direct airway injury and subsequent formation of conduit-airway fistulas. These complications, often under-reported, are technical in nature, and can be avoided with meticulous avoidance of direct thermal insult to the airway during peri-tracheal esophageal mobilization and lymphadenectomy [17].

LEARNING CURVE

The MIE operation remains a highly complex laparoscopic and thoracoscopic procedure, and complete inexperience with minimally invasive skills can be expected to lengthen the learning process. However, due to the sophistication of the robotic technology, the surgeon learning curve may be attenuated, although a direct measure of this supposition is difficult to attain [8, 36]. In 2013, Hernandez attempted to define when proficiency is achieved in robotic esophagectomies by evaluating a 52-patient cohort divided into increments of ten. Then, operating times, conversion to open operations, and post op complications were examined. Near proficiency was observed around 20 cases. Following completion of 20 esophagectomies, operating time decreased from 514 to 397 minutes ($p < 0.005$). No significant differences in complications were identified in any 10 patient section [9].

From a posterior approach, Kim et al. studied a surgical oncologist with no prior thoracoscopic experience performing the chest dissection with console times being halved from the first six patients to the next fifteen [37]. Similar conclusions can be drawn from Putambekar et al.'s updated cohort where proficiency was likely achieved early on. The total operative time for the first 32 patients was 210 minutes with the average only decreasing to 204 minutes when an additional 51 patients were included [28].

The most robust experience regarding the learning curve in completely robotic RAMIE includes a cohort of 100 patients from Memorial Sloane Kettering. The study design ensured a dedicated operating room team remained constant including 2 attending surgeons and specific anesthesiologists and operating room staff that were familiar with the operation. Median operative time decreased from 447 minutes to 357 minutes between the two fifty case cohorts. Median operative time decreased to 370 minutes between cases 30-45 with the nadir between cases 40-45, likely representing the point of proficiency. 30-day mortality was 0% and 90-day mortality was 1%. Conversion rates decreased from 13 in the first 50 cases to two in the last 50 cases. Estimated blood loss and overall complications also decreased. The number of lymph nodes harvested also increased but this did not reach statistical significance. The authors advocated that excellent outcomes can be achieved by adhering to key programmatic principles including a consistent operative team, pre-execution planning and ongoing critique of outcomes and refinements in technique [10].

CONCLUSION

In summary, RAMIE has been performed by multiple approaches and, like open esophagectomy, the most efficacious method remains a matter of some equipoise. From single institution studies, surgeons have shown the RAMIE operation can be performed safely with low mortality. The morbidity mimics those complications seen with the previously described minimally invasive or open operations. The data published demonstrates that a sound index oncologic operation can be performed. Data regarding long-term survival is still accruing, given the relative infancy of these procedures. As a final, but equally important and often neglected consideration, significant data is lacking in the utility of the ergonomically superior robotic technology to decrease work-place related injuries and enhance the health and lengthen the career of operating surgeons.

INTRODUCTION

Surgical management of esophageal disease represents a unique challenge for physicians. The esophagus abuts many vital organs as it travels from the neck, through the chest, and down into the abdomen. Surgeons must therefore have a high degree of comfort operating in three distinct anatomic compartments using a wide variety of operative techniques and approaches. As the field of minimally invasive esophageal surgery grows, safer and more efficient techniques have made care of this complicated organ easier. Robotic surgery is the newest development in this progression, and its use is becoming increasingly more common in the treatment of a variety of esophageal conditions. Rather than highlight the indications for surgery, which for the most part is currently well established with minimal controversy, this chapter will focus on the surgical management and challenges of benign esophageal diseases, specifically that of achalasia, paraesophageal hernia, gastroesophageal reflux disease (GERD), and esophageal diverticula.

Achalasia

Achalasia is a fairly uncommon condition that affects approximately 1 in 100,000 adults annually [1]. Surgeons first became involved in the management of this debilitating disease in 1913 when Ernest Heller developed the technique of performing a transabdominal myotomy of the distal esophagus. Subsequent developments led to development of an open transthoracic approach. The first foray into minimally invasive management of achalasia

came in 1992 when Pellegrini et al. published a case series of 17 patients treated by either thoracoscopic or laparoscopic approach [2]. As the field of minimally invasive surgery has grown, laparoscopic Heller myotomy has become the mainstay of surgical management for achalasia. The laparoscopic approach has been shown to have equal rates of efficacy at reducing symptoms of dysphagia when compared to the open approach, with the added advantages of shorter hospital stay, less post-operative pain, and decreased hospital costs [3-6]. In the early 2000s, the first robotic Heller myotomies were performed [7]. The robotic platform allows for better visualization of the hiatus as well as the transecting of muscle fibers during myotomy to avoid injury to the mucosa. The increased range of motion of the robotic arms and wrists facilitates a greater degree of ease for the dissection of the muscle and mediastinum [8]. There have been several small studies comparing the safety and efficacy of robotic versus laparoscopic approach. Maseo et al. published a meta-analysis which included more than 2,100 patients and found that while the efficacy of the two techniques was similar, with robotic Heller myotomy had a decreased rate of esophageal perforation when compared to laparoscopic surgery (0% vs. 11%) [9]. These findings have been corroborated by several other studies [10, 11] and suggest that a robotic approach to achalasia will become increasingly popular.

Gastroesophageal Reflux

Surgical management of GERD via fundoplication is a safe and effective way of treating those patients whose symptoms are refractory to medical management. Historically, this surgery was performed open either via abdominal, transabdominal or thoracic open approach, until in 1991 when Dallemagne et al. reported a case series of 12 laparoscopic Nissen funduplications. He concluded that a minimally invasive approach was both safe and effective at managing patient symptoms [12]. These findings have been supported by subsequent studies that have compared minimally invasive techniques to open surgeries. In one randomized trial that followed 148 patients over 10 years, the authors found that laparoscopic techniques are equally effective at managing patient symptoms and improving quality of life, with the added advantage of fewer reoperations [13]. Other studies have also noted that laparoscopic surgeries result in shorter hospital stays, faster recovery, and better pain control [14]. More recently, robotic systems have been used to perform anti-reflux procedures. To date there are few studies directly comparing robotic versus laparoscopic techniques, but the few trials that do exist show similar rates of efficacy and complications between the two approaches [15-16]. Robotics did have an advantage over laparoscopy in anti-reflux reoperations with fewer conversions to open, recurrences, and shorter operative times [17, 18].

Paraesophageal Hernia

Hiatal or paraesophageal hernias are fairly common findings and may cause a significant amount of morbidity for patients. Traditional repair of this condition was done by an open, typically thoracic or transabdominal, approach. However, as with other fields of esophageal surgery, a minimally invasive approach to the treatment of paraesophageal hernias has

become increasingly popular since the first laparoscopic repair was performed by Cuschieri in 1992. He documented a case series of 8 patients successfully treated via a minimally invasive approach [19]. Since then, there have been many studies comparing the two techniques. While symptomatic relief and patient satisfaction have been shown to be equivalent between laparoscopic and open approaches [20, 21], minimally invasive surgery has thus far proven superior in terms of patient safety and complication rates. Scholtzman's review of the National Inpatient Sample database reviewed more than 60,000 patients undergoing paraesophageal hernia repair (PEHR). He found that patients undergoing minimally invasive surgery were less likely to experience post-operative bleeding, infection, organ failure, and mortality while also having shorter hospital stays [22]. Mungo et al. found similar results evaluating more over 8,000 patients in the National Surgical Quality Improvement Program (NSQIP) database. Their data showed that 30 day mortality for laparoscopic repair is almost 3 times lower than open approach, and rates of respiratory, cardiac, and infectious complications similarly favored laparoscopic repair [23]. There has been some concern about the durability of laparoscopic repair when compared to open due to several studies showing higher rates of radiographic recurrence in laparoscopic compared to open techniques. Despite this finding, patients do not report any difference in clinical symptoms or overall satisfaction, suggesting this finding may not be clinically significant and should not deter surgeons from a minimally invasive approach [24, 25]. There is little data currently that compares laparoscopic to robotic outcomes. The limited data that does exist indicates similar rates of success and complications between robotic and laparoscopic techniques [26]. With greater adoption of robotic technique for this procedure, both by thoracic and general surgeons, we should expect answers to this question to be answered via large databases in the near future.

Esophageal Diverticula

Diverticula of the esophagus are quite rare, appearing in less than 1% of upper GI studies [27]. They may occur anywhere along the esophagus, requiring a variety of approaches to management depending upon their location. Excluding proximal diverticula, the traditional open approach via either an abdominal or thoracic incision has lost favor in comparison with minimally invasive techniques, beginning with the first laparoscopic diverticulectomy in 1998 [28]. Because of the uncommon nature of this disease, data comparing different surgical approaches is somewhat limited. However, the studies that do currently exist show significant reduction in mortality (1.6% vs 6%) as well as leak rate (7% vs 10%) with a laparoscopic compared to open approach [27]. There is minimal data on the use of the robotic platform in treatment of esophageal diverticula, mostly single center retrospective reports, but the robot appears to offer superior visibility and ease of dissection compared to laparoscopic surgery, with similar patient outcomes [29].

OPERATIVE TECHNIQUE

Both the Xi and Si da Vinci robotic system (Intuitive Surgical, Sunnyvale, CA) will be discussed for set up and port placement. The operations themselves are essentially identical for either system.

Pre-Operative Planning and Testing

The pre-operative planning for any of the four benign esophageal processes to be discussed in this (achalasia, GERD, paraesophageal hernias, diverticula) should follow the same planning that goes into an open or laparoscopic procedure as robotics should essentially be considered as another mode of minimally invasive surgery.

Room and Robotic Set Up

Our room is fitted with a TruSystem 7000dV operating table (Trumpf Medical, Saalfeld, Germany) which allows for synchronized movement between the Xi and the table while the robot is docked. The patient is then induced and intubated with a single lumen endotracheal tube. Two large bore IV's are placed, foley, intermittent pneumatic compression devices of the lower extremity are placed, subcutaneous heparin, and pre-operative antibiotics are given. A foot plate is placed on the bed, pillow placed under the knees, and a strap is placed over the thighs. A Bair Hugger (3M, Maplewood, MN) is placed over the over the lower legs.

If the patient needs a pre-procedural esophagogastroduodenoscopy (EGD) then we usually do it at this time, but is not often the case. If an EGD is performed pre-incision then we may leave it in the esophagus and place the umbilical cord under the pillow. If not, than an orogastric tube is often placed for decompression.

Si Port Placement and Docking

Once the patient is prepped and draped we usually use a Hassan open technique for gaining access to the abdomen placed just left of the umbilicus. This 10-12 mm port will then serve as our assistant's access port. It is perfectly reasonable to use other access techniques (e.g., Veress needle or optical ports with separate 5mm camera) based either on surgeon preference or patient characteristics (e.g., prior surgery). Before insufflation, we visually confirm trocar placement within the abdominal cavity. Once correct placement is ensured, we insufflate to 15 mmHg, and further port placement is performed under direct visualization.

A 5 mm trocar is placed laterally on the patient's right below the liver and medial to the bowel for the articulating liver retractor. A 10-12 mm blunt tip disposable trocar is placed midline two-thirds of the way down from the xiphoid for the 12 mm Si camera. Two 8 mm metal da Vinci ports are placed a hands breadth left and to the right of the camera port (approximately 10 cm). A third 8 mm port is placed a hand's breadth away from the right port (patient's left) (See Figure 1).

The liver retractor is placed and held in place by articulating arm attached to the bed. The patient is placed in steep reverse Trendelenburg. (Some surgeons prefer to bring the robot in first and then place the robot in reverse trendelenburg. The key is to do it before docking as you cannot change the angle of the bed while the robotic arms are docked on the Si.) The robot is then brought in over the patient's head and docked (See Figure 2). The docking for the Si makes it more difficult for anesthesia to access the patient, especially if you will need accesses to the mouth later in the case (i.e., to place a bougie, nasogastric tube, or perform an EGD).

Special consideration for port placement should be considered for two specific groups of patients: those with narrow waists and redo surgery. The former can be very difficult for port placement as ideally the Si ports/arms need approximately 10 cm of space (hence a hand's breadth), but this is not always feasible in very narrow patients. The surgeon will need to adapt to the anatomy. As for redo surgery, port entry and placement may be the most difficult aspect of the case. Initial entry to the abdomen and subsequent lysis of adhesions may be required. Be prepared and be patient, as this may require a significant amount of time to accomplish. The reward for your diligence is the ability to complete the case robotically and perform a high quality procedure.

Figure 1. Si port placement.

Figure 2. Si docking configuration.

Xi Port Placement and Docking

There are some significant docking differences between the Si and Xi. Firstly, we place all the ports at the level of the umbilicus except for the 5 mm liver retractor (See Figure 3). The Xi instruments are longer than the Si and to accommodate we lower the placement. In theory, we like to keep the working instruments a good deal below the targeted anatomy. We apply this to all the robotic surgery we perform, and it has been very helpful. The arm ports so close to the assistant port makes it a little harder for the assistant port, but we have learned to work around this- some surgeons don't use it at all. Secondly, the camera port is replaced with an 8 mm da Vinci metallic port. Thirdly, we use a 12 mm da Vinci port for Endowrist stapler instead of an 8 mm port just to the right of the camera port (patient's let) for paraesophageal hernia repairs (PEHR) in case they need a lengthening procedure. Fourthly, the docking of the Xi can occur on either side of the patient due to the rotating boom that allows greater freedom and oral access to the anesthesiologist. Finally, we do not use the targeting feature of the Xi because we feel that we are able to control exactly where we want to be manually (See Figure 4).

Figure 3. Xi port placement.

Figure 4. Xi docking configuration.

ACHALASIA

Once the robot is docked, regardless of system, the same instruments are placed: cadiere forcep in the surgeon's left "hand", curved bipolar in right and small graptor in right lateral arm. (A vessel sealer or harmonic can also be used.) The pars flaccida is opened first which allows perfect access to right crus and the hiatus. We continue our dissection by taking down the thin veil of tissue between the right crus and esophagus making sure to not damage the right crus fascia. This dissection is carried superiorly and is continued laterally to the left lateral aspects of the hiatus also making sure not to damage the fascia along the left crus.

Throughout the dissection the 4th arm, which is controlling the small graptor, has a rolled up gauze sponge and is being used as a passive retractor. We make a concerted effort to avoid grasping the tissue for traction and instead rely almost entirely on passive traction.

There are a few ways to approach the myotomy and fundoplication. Our preference is to use the bipolar and cadiere to create a window between the esophagus and the mediastinum for the intra-thoracic esophagus in order to create the myotomy. If not, then we prefer to use the vessel sealer. (This can also be used later to take down the short gastrics if so desired for the partial fundoplication.) It is important to ensure one has enough visible esophagus in the chest by dissecting out approximately 5-8 cm above the hiatus before starting the myotomy. We do not routinely dissect out the posterior aspect of the hiatus, but if there is a concomitant hernia this may be necessary.

Once the dissection has been completed, our tool of choice is the hook cautery which is also used in the right arm replacing the bipolar. The myotomy can be performed a myriad of ways; just as long as it is effective and safe (e.g., cold scissors, harmonic scalpel, etc). Some surgeons like to use a bougie while doing the myotomy; we routinely use 50 French, which is placed by anesthesia and confirmed as it is placed under direct visualization with the robotic camera.

We begin the myotomy usually at the gastroesophageal junction (GEJ) and work proximally along the esophagus. Both the right and left graspers/forceps are used to help facilitate the dissection by gently pulling the muscle laterally. We generally perform approximately 5-7 cm myotomy vertically along the esophagus and then open the proximal stomach another 2-3 cm. The fundamental aspect of this part of the procedure is preventing an enterotomy. The best way to do this is through a meticulous dissection with your instrument and avoiding any inadvertent contact, blind dissection, or a delayed heat injury. If you do see an enterotomy, repair it immediately with an absorbable suture. If you are still very worried an anterior fundoplication can help buttress an intra-abdominal injury.

What separates a surgical Heller myotomy from an endoscopic procedure (i.e., Peroral Endoscopic Myotomy aka POEM) is the ability to perform a fundoplication. The most common fundoplication after myotomy is an anterior 180 degree (Dor) fundoplication that lies on top of the myotomy. We do not recommend leaving the Heller without any fundoplication as there can be significant associated reflux afterwards.

An EGD can be performed at this time to ensure that there is adequate length to the myotomy, but this is not always necessary. We keep the EGD cart in the room in every procedure just in case.

Once the myotomy is completed, we close the crura with interrupted 0 silk stitches so that it is closed but not too tight. To accomplish this, we use the mega suture cut needle driver in

the right hand. The key to a good closure is ensuring that the crura fascia remains intact during dissection as this is the aspect of the muscle that provides crural integrity.

There are several keys to performing a good fundoplication: 1) taking enough short gastrics so that the wrap lays tension free behind the esophagus once pulled through; 2) a meticulous posterior dissection so the wrap pulls through easily if it is a 270 degree posterior fundoplication; 3) identification of the anterior and posterior vagus nerve and avoiding them; 4) making sure that you are able to visualize the fundus and the esophagus while sewing. The last point is where many surgeons' wraps fail because the stomach has not been secured appropriately thus potentially herniating/slipping through the plication.

Figure 5. Anterior fundoplication.

An anterior fundoplication is very easy to perform and requires only a few stitches. Many times it does not require taking the short gastrics, but it should lay tension free. If it does not then we recommend dissecting enough of the lateral attachments of the stomach until it does so. To secure the wrap we place the first stitch at the 3 or 4 o'clock position along the left crus with one bite along the left crus and another into the fundus using a 2-0 silk stitch. We then place another two to four 2-0 silk interrupted stitches in the same manner working counter clockwise to the base of the right crus (Figure 5).

Again, some surgeons like to perform an EGD at this point before closing to ensure the myotomy is wide open. At this point the procedure is completed and closing is performed in the usual manner. Generally speaking, 8 mm port sites do not require facial closure.

ESOPHAGEAL DIVERTICULA

The three areas of the esophagus that can develop diverticula (proximal, medial and distal) each represent a different disease process with different approaches to repairing normal esophageal luminal flow. At this time there is no robotic approach for the proximal diverticula which is a result of a hypertensive cricopharyngeal muscle. The mid esophagus

diverticulum are usually caused by an issue with a malignant or infected mediastinal lymph node and is a true diverticulum. This chapter will focus only on the lower esophageal diverticula which are usually secondary to an underlying abnormality of the lower esophageal sphincter (LES; i.e., secondary to achalasia). In such cases, the underlying esophageal pathology (e.g., Heller myotomy in the case of achalasia) must be addressed at the time of the diverticulectomy.

Regardless of robotic system, Xi or Si, the approach to a diverticulectomy is similar as the initial aspects of a Heller myotomy just discussed except we recommend a complete dissection around the esophagus so that it is fully visualized. Once the entire esophagus has been dissected and cleared of the crura the diverticula should be visualized. The muscle fibers of the esophagus are spread in order to visualize the entire neck of the diverticula. A bougie can be placed carefully by anesthesia to ensure that the esophageal lumen is not narrowed during stapling (approximately 50 French). At this point the diverticula can be stapled with any laparoscopic stapler through the assistant port or the da Vinci Endowrist stapler (blue load) depending on the technology available. (A 12 mm da Vinci metallic port is required for the Xi stapler.) The specimen is then removed in a sterile bag through the assistant port.

As most distal diverticula are secondary to achalasia, a myotomy and fundoplication as discussed in the prior section would need to be performed. The myotomy should be approximately 180 degrees from the staple line.

ANTI-REFLUX PROCEDURES

The room and port set up for a robotic fundoplication procedure is exactly the same as was described for achalasia. The one major difference is that we do like to place a bougie, at least 54 French, before closing the crura and doing the fundoplication. The additional crucial aspect to consider before performing an anti-reflux procedure is that the patient absolutely will benefit from it. This can be confirmed by the appropriate tests pre-operatively. There is nothing worse than having to re-operate on someone because the proper procedure was not done initially.

In the proceeding section, the anterior (Dor) funduplications was discussed. A posterior or 270 (Toupet) fundoplication offers greater anti-reflux relief than an anterior fundoplication without some of the associated issues of a complete wrap. The value of these procedures over a complete 360 degree fundoplication (Nissen) for reflux should be performed based on surgeon preference and patient characteristics.

As stated before, the critical aspects of performing a technically sound fundoplication is: 1) making sure there is not a sliding or paraesophageal component to the reflux, and if there is, then it must fixed appropriately; 2) mobilizing fundus by taking enough short gastrics so that the wrap lays tension free behind the esophagus once pulled through; 3) a meticulous posterior dissection so the wrap pulls through easily; 4) identification of the anterior and posterior vagus nerves and avoiding them; 5) making sure that you are clearly able to visualize the fundus and the esophagus while sewing. This last point is where the wrap fails because the incorrect tissues have been sutured leading to the stomach to herniate/slip through the plication due to approximating fatty tissue to the esophagus rather than the fundus. Many

times this is avoided by taking the fat pad along the lesser curve/GEJ, which we do on every case. This can also provide some additional esophageal length if that is an issue.

For either the complete or posterior fundoplication, we mobilize the short gastrics by placing the vessel sealer in the right hand which replaces the bipolar. There are multitudes of ways to take down the short gastrics we like the vessel sealer for its ability to reliably ligate vessels/tissues and that it can act like as an additional grasper and dissector. This can be very helpful while completing the last of the dissection along the left crus and the decussation if there are adhesions.

We then slide the fundus behind the esophagus and it should slide easily through. There are many different ways to perform a 270 degree fundoplication, but our preference is to place a 2-0 silk from the superior aspect of the fundus into the lateral aspect of the esophagus. We start on the patient's left and then do the same thing on the right. Once completed, we move about a cm below and place another row of 2-0 silk stitches starting on the patient's left fundus to the lateral edge of the esophagus, and repeat on the patient's right. A third and final row is placed just distally to the second. We secure the fundoplication to each of the crus with 2-0 silk (See Figure 6). The entire length of the fundoplication should be approximately 2-3 cm.

For a 360 degree fundoplication the fundus is brought along behind the esophagus, like the 270-degree posterior wrap, and should lay tension free behind the GEJ. An interrupted 2-0 silk superiorly is placed between the two edges of the fundus. Another interrupted 2-0 silk is placed between the fundus and the esophagus and through the esophagus opposite fundus. A third interrupted is placed inferiorly between the fundus edges. The stitches are then tied down. A crus stitch is placed laterally to the fundus as a securing stitch on either side. The bougie is removed (See Figure 7).

Figure 6. Posterior fundoplication (Toupet).

Figure 7. Complete fundoplication (Nissen).

PARAESOPHAGEAL HERNIA

PEHR is a complex multi-step operation with each part being performed fastidiously to prevent recurrence. Most recurrences are a result of either missing or skipping any of these steps. There are currently some controversies surrounding PEHR: type of fundoplication, use of biologic mesh to close hiatus, lengthening procedure, optimal time to repair. The described procedure is what we feel to be best practice based on the most current literature and on years of evidence in both open and laparoscopic PEHR- not just robotics.

Each surgeon will have their own style and preference, but overall should adhere to following principles: 1) surgically remove the entire sac; 2) preservation of both vagal nerves; 3) ensuring crura fascia integrity is maintained; 4) 2-3 cm of intra-abdominal esophageal length once stomach is delivered from chest; 5) ligating the short gastrics so that there is a tension free mobilization of the fundus for potential fundoplication.

Patient position, port placement (including the 12 mm da Vinci port for Endowrist stapler if you think you may need a gasatroplasty) is as discussed in prior sections.

The pars flaccida is opened initially with the energy source of choice (we prefer the curved bipolar to start) working to dissect out the right crus. As the tissue thickens we move to the vessel sealer as we like the wristed forceps and grasper capabilities in addition to its ligating energy. We separate the sac from the right crus making sure not to damage the integrity of the fascia while working our way into the intra-thoracic component of the hernia. As we peel the sac back we try not to enter the pleura. Sometimes this is unavoidable due to adhesions and a simple stitch or cautery can seal it back up. (Hardly ever is a chest tube required intra-operatively.) Moving in a clockwise fashion from the patient's right to the superior/anterior aspect, the sac is dissected while also working your way to the posterior. Usually it is initially very challenging to remove the sac along the 5 or 6 o'clock part of the sac along the base of the left crus.

At this point we usually transition to taking the short gastrics and the lateral attachments. We start inferiorly and work superiorly along the greater curve. By approaching it this way you are eventually able to complete the dissection posteriorly along the decussation and left crus safely from the greater curve.

Once this is completed we usually measure how much intra-abdominal esophageal length we have. Almost always, we have to go back and dissect more of the proximal esophagus. Our routine is to always take the dissection to the inferior pulmonary veins in order to get enough length.

If after this maneuver there is still not enough intra-abdominal length several surgeons have advocated for the use of wedge gastroplasty using the several fires of the green da Vinci Endowrist stapler. In our own practice we have liberally employed a gastroplasty and have had no complications in our limited series (7 patients). To perform the gastroplasty, we then have anesthesia place between a 51-60 French Savory bougie down the esophagus. (Ensure there is no orogastric or nasogastric tube before stapling.) We usually start the stapling at the more distal aspect of the wedge along the greater curve holding it up with the cadriere in our left hand using a green load (See Figure 8). The first fire is perpendicular to the bougie and the second, and third if necessary, is parallel to the bougie (See Figure 8 A - D). Once completed, it is removed via the assistant port in a sterile bag.

Figure 8. Creating gastroplasty. (A) First Staple bit; (B) Second Staple Bite; (C) Third Bite; (D) Final Gastroplasty.

The fat pad along the lesser curve is excised along with any excess sac that would make a fundoplication difficult. Be sure to avoid injuring the vagus nerve during the dissection. Closure of hiatal crura is as discussed in prior section with interrupted 0 silks and mega suture needle driver. If you are unable to bring the crura together we advocate initially reducing insufflation pressure. If that does not work a relaxing incision can be made parallel to the left crus along the lateral diaphragm and patched at the end of the case with mesh (we recommend vicryl due to low cost). We do not advocate using biological mesh to close the gap in the hiatus although many surgeons/authors espouse this technique. As thoracic surgeons we see many complications from this technique and have found that closing it primarily is usually feasible. In very difficult cases where relaxing incision does not help to close the crura we have employed the COR-KNOT system (LSI Solutions, Rochester, NY) with great results.

Once this is all completed, we advocate employing a fundoplication; our preference is a posterior wrap, but we leave this up to surgical discretion. The robot is then undocked. We only close the 12 mm port under direct visualization using a Carter Thomason guide (Cooper Surgical, Trumbull, CT) and a suture passer.

CONCLUSION

As stated at the beginning of the chapter there are few studies that compare robotic benign esophageal foregut surgery to the other modalities. Almost all are retrospective and are not propensity matched. We do know from these studies that the outcomes are safe and for the most part equivalent. Increased cost is an issue usually in regards to operative time, but judicious use of resources and improved operative time can usually overcome these issues. The big gain in robotic benign esophageal surgery for surgeons is the ability to be minimally invasive and perform a high end operation due to the multiple advantages the robot brings. We look forward to single site surgery, perhaps randomized control studies, as well as new technology from new partnerships. Regardless, robotic surgery's future looks very bright.

INTRODUCTION

Robotically-assisted mitral valve procedures (RMVP) represent a major advancement in the field of minimally invasive surgery, which is the blueprint of the current surgical era. It is the most common type of robotically-assisted cardiac surgeries practiced today. These procedures involve both mitral valve repair and replacement with or without additional procedures such as the Maze procedure for atrial fibrillation. Similar to other minimally invasive surgeries, the main goal is to lessen the operative trauma and postoperative pain that patients have to endure. Thus, instead of the conventional sternotomy incision, this procedure is performed via five smaller intercostal incisions without rib-spreading. The procedure can be done totally endoscopically. This means that no portion of the operation is done by looking directly into the chest, due to the small port size, and all visualization is with the robotic camera.

Other benefits associated with minimally invasive cardiac surgeries include; better cosmetic results with minimal scarring, less amount of bleeding, lower risk of infection, as well as shorter hospital stay and recovery periods. Despite being a controversial issue, a cost-effectiveness benefit has also been reported, attributed to shorter hospital stay and minimal use of pain and antibiotic medications.

Since the first RMVP in 1998, [1] the procedure has endured many challenges, uncertainties and discredit. Through the process of continuous modulation, the current technique practiced today has evolved. Multiple stages of modification and testing were

required to optimize the conduct of this procedure, involving; robotic equipment, surgical instruments, surgical technique, health-care team organization and preoperative assessment and planning. Reproduction of experiences of different surgical teams has also contributed to identifying standard patient selection criteria.

This chapter will discuss the current indications, contraindications, advantages, disadvantages, preoperative preparation, operative technique and complications of RMVP, along with tips to improve outcomes [2].

INDICATIONS FOR MITRAL VALVE REPAIR

The American Heart Association (AHA) and the American College of Cardiology (ACC) 2014 guidelines for the management of patients with valvular heart disease have categorized patients into five groups based on their level of degenerative mitral regurgitation (MR) (See Table 1). In general, for primary MR patients surgical repair should be done in those with stage D and C2 disease, Class I recommendation. Other Class I recommendations for primary MR intervention are those patients with posterior leaflet disease, those with anterior leaflet disease or bileaflet disease and successful repair is deemed possible, and when a concomitant surgery is planned. The evidence for secondary MR is less robust, however the AHA/ACC recommend that surgical interventions is warranted in patients with stage D or C who are undergoing either CABG or AVR (Class IIa), those with stage D disease with poor functional status NYHA class III/IV, and those with stage B disease who are undergoing any other cardiac surgery (Class IIb for both).

Table 1. Stages of mitral regurgitation for both secondary and primary causes

Grade	Definition
A	At risk for development of MR
B	Diagnosed MR with disease progression
C1	Severe disease in asymptomatic with preserved left ventricular function (EF > 60%)
C2	Severe disease in asymptomatic patient with early-reduced left ventricular function (EF < 60%)
D	Severe MR and symptomatic

PATIENT SELECTION FOR ROBOTIC MITRAL VALVE SURGERY

Patients are candidates for robotic mitral valve surgery if they meet the criteria set forth by the AHA/ACC guidelines. The robotic approach is done through the right chest, thus any thoracic pathology in the region may be a contraindication. While general contraindications to cardiac surgery also apply to robotic surgery, lists of specific absolute and relative contraindications to the robotic approach are outlined in Table 2. In our experience, 98% of isolated mitral valve procedures can be done robotically. The 2% consists of high-risk patients unsuitable for any type surgery, severe mitral annular calcification, severe peripheral vascular disease, ascending aortic aneurysm >40mm, and severe adhesions in the right pleural space. All of these are relative not absolute contraindications. Different surgical groups have different philosophies on this with some groups being more selective for extremely low risk

patients and including other exclusions such as redo surgery. We have not found redo surgery to be a problem and in fact, it can be easier than a redo sternotomy if there are limited adhesions in the right pleural space.

Table 2. Absolute and relative contraindications for robotic mitral valve surgery

Absolute	
Previous right thoracic surgery	Coronary artery disease requiring CABG
Severe peripheral vascular disease	Dilation of the aortic root or ascending aorta
Mild to moderate aortic valve insufficiency	Calcifications of the mitral annulus
Moderate to severe aortic root or ascending aorta calcification	Severe chronic pulmonary disease
Relative	
Previous sternotomy	Mild to moderate peripheral vascular disease
Chest deformities	Mild to moderate aortic valvular disease either insufficiency or stenosis
Additional valvular pathology involving other heart valves	Moderate chronic pulmonary disease

PREOPERATIVE WORK-UP

Patient work up should always begin with a thorough and in-depth history and physical. Those patients who meet the AHA/ACC criteria for surgical intervention and have no contraindications to robotic surgery found on history and physical are then progressed to preoperative imaging [3]. Computed tomography (CT) of the chest, abdomen and pelvis with intravenous contrast is required. This allows for imaging of the vasculature for possible bypass cannulation sites, assessment of the aorta for dilation or excessive calcifications, and any anatomical abnormalities not seen on physical exam. One of the most important things to look for is the presence of intraluminal thrombus. Such thrombus can cause strokes if retrograde femoral arterial perfusion is used. Patients with suspected or at risk for coronary artery disease and men >40 and women >50 years of age may undergo either traditional cardiac catheterization or CT coronary angiogram. Those with significant pulmonary disease or concern for severe pulmonary hypertension on echocardiogram may undergo right heart catheterization as well. A high quality (usually 3D) transesophageal echocardiogram is optional preoperatively but is extremely helpful in preoperative planning. A preoperative risk stratification assessment such as the Society of Thoracic Surgeons (STS) score should also be calculated to aid the surgeon in preoperative planning and for patient education.

OPERATIVE TECHNIQUE FOR TOTALLY ENDOSCOPIC ROBOTIC MITRAL VALVE REPAIR

The technique used by the author is described below in general terms to present an overview of the operation. Specific pitfalls and troubleshooting are described later. See Table 3 for brief overview.

1. Patients are placed supine on the operating table, general anesthesia is induced and the patient is intubated with a left angled double-lumen endotracheal tube to allow for deflation of the right lung during the initial portions of the procedure and at the end of the procedure. Some groups use a single lumen tube with or without a bronchial blocker instead.
2. Anesthesia routinely places bilateral arterial lines. We prefer bilateral brachial arterial lines so that we can be certain of the relative pressures of the right and left arms during the procedure. Also placed is a right single-lumen internal jugular central line for later use by the surgeon for bicaval cannulation, a percutaneous coronary sinus catheter for cardioplegia, and a percutaneous pulmonary artery vent both of which are placed under fluoroscopy and transesophageal echocardiogram guidance. Foley bladder catheter for monitoring of body temperature and urine output is also placed at this time.
3. The right chest is bumped up to an angle of 15 degrees. The neck, chest, abdomen, pelvis, and legs are prepped and draped.
4. Depending on preoperative imaging a right or left groin cut-down is done and the vessels are assessed for possible cannulation. If the vessels are suitable for access, a purse string suture is placed in the femoral vein for later use. Axillary artery cannulation is an alternative in patients with descending thoracic aortic intra-luminal thrombus as this reduces the incidence of stroke. This strategy could include the use of a transthoracic aortic cross clamp or placement of the endoballoon via the femoral artery or in selected cases, through the axillary artery as well.
5. Right lung isolation is initiated at this point and four 8mm robotic ports are placed in the right chest with one 12mm working port placed in the 4th or 5th intercostal space in the anterior axillary line. Figure 1
6. Three 14 gauge angiocatheters (5 ½ inches long) are placed in the right lateral chest with 0 silk suture loops to be used later as retraction sutures.
7. A 12-french peel-away sheath along with a 12-french sump drain are placed into the right chest for later use.
8. Venous cannulation is performed next. This is done using a 22 or 24-french multi-stage Edwards Lifesciences (Irvine, CA) venous cannula into the common femoral vein that had been previously exposed via a cut down. The Seldinger technique is used and under echocardiogram guidance the tip is placed in the superior vena cava. The cannula was then attached to the cardiopulmonary bypass circuit.
9. The femoral artery is cannulated with an Edwards Endoreturn 21 or 23F cannula via Seldinger technique and under echocardiogram guidance to ensure the wire is in the aortic lumen. A 4-0 Prolene (Ethicon, Inc., Somerville, NJ) purse-string is used. We routinely place a 6F or 7F wire wrapped sheath in the distal femoral artery in an antegrade fashion as a distal limb perfusion technique. We connect the side port of the sheath to a branch off the arterial line to ensure limb perfusion. Many groups use these selectively or not at all. We also use distal limb oximetry to monitor limb oxygen saturation throughout the case. Figure 1B.
10. At this point the right single-lumen internal jugular catheter that had been previously placed was exchanged over a wire to a 16-french superior vena caval drainage catheter. This was done to achieve bicaval drainage.
11. The robot is then docked. Figure 2

12. The tendon of the right hemidiaphragm is tented up with a robotic long tipped forceps and a CV2 (Gore Medical, Flagstaff, AZ) pledgeted mattress suture is placed, tied down, and exteriorized via the most inferior lateral chest wall angio-catheter. This is done to improve exposure and protect the diaphragm and liver from injury.
13. Next the pericardium is opened from the inferior vena cava over to the aorta. Once this has been done and adequate exposure is achieved, cardiopulmonary bypass is initiated. If exposure is challenging, the surgeon can go on bypass prior to opening the pericardium.

Table 3. Brief outline of robotic mitral valve surgery

Nerve block, patient to room
Double Lumen ETT, foley, bilat brachial a-lines
RIJ SLC, proplege, PA vent (TEE+Fluoro)
Fem expose, lung down, ports, 14GX3, LA sump
Heparin-Fem V, leg shunt, FA, endoballoon, SVC
Dock bot, diaphragm suture, open pericardium
Pericardial retraction, CPB, checklist, arrest
Atrial Entry, LA retraction stitch, LAA closure
Valve analysis, repair, static test
Close LA, pacer wire, blake in pericardium
De-air, tie LA suture, remove instruments
Gradual lung re-inflation, wean off CPB, TEE
Decannulate, Protamine, RVATS
Close, remove PA vent, proplege, SL ETT, ICU

Figure 2. Docking of the robotic arms and camera.

14. Pericardial retraction sutures are placed and exteriorized through the angio catheters by using the previously placed silk suture loops to grab the retraction sutures and exteriorize them outside the body. They are then affixed with a hemostat.
15. At this point the heart is arrested with the endo balloon in the ascending aorta. The author uses 30mg of adenosine followed by 1 liter of antegrade high potassium, cold, del Nido cardioplegia given into the ascending aorta. Then 500 milliliters of

retrograde cardioplegia is given as well. If at 1 hour cross-clamp things are going well or the repair is completed, no further cardioplegia is given. If it appears the procedure may be prolonged beyond 90 minutes cross-clamp time, a second dose is given of 750 cc retrograde cardioplegia.

16. After adequate arrest of the heart, the left atrium is opened. This is done through the oblique sinus behind the inferior vena cava in Waterston groove.
17. The intracardiac sump drain is placed into the left pulmonary veins.
18. The author routinely closes the left atrial appendage, which is done at this point of the operation. This is performed using a CV4 Gore-Tex (CV2 (Gore Medical, Flagstaff, AZ) suture in a double layered fashion. In part we do this to improve exposure of the P1 region and the left commissural area. We also place a retraction suture to retract the posterior left atrium down to the pericardium to improve exposure of the posterior P2/P3 portion of the valve.
19. The valve is inspected at this point and static tested to evaluate how best to repair the valve. We use the da Vinci Xi suction irrigator to perform the static test as this allows for very precise testing.
20. Once the area of pathology is identified, a strategy is developed which might include either resectional or non-resectional approaches. In most cases of prolapse, we use neochords (NeoChord, St. Louis Park, MN) more and more. All the neochords are places without tying them (two passes of each needle) and placed on a hemostat outside the body. We then static test again and perform dynamic adjustment of the chord length for each Neochord. We then grab the sutures with a robotic debakey and have the bedside assistant place 12 knots on each.
21. The annulus is sized next. The appropriately sized flexible band is then placed and sutured with a CV4 mattress suture, one at each trigone. A running horizontal mattress suture is also placed. Alternatively, in the case of functional mitral regurgitation or ischemic mitral regurgitation, we will use a semi-rigid complete ring with interrupted 2-0 ethibond sutures secured with Cor-Knots (LSI, Inc., Rochester, NY).
22. The valve is then again static tested for compliance and a left ventricular sump drain was placed across the valve.
23. Atrial retraction sutures are removed and the left atriotomy is closed with a CV4 Gore tex suture.
24. The aorta is de-aired the endo balloon is deflated ending the crossclamp time.
25. A single pacing wire is placed into the right ventricle and a 24 French Blake drain is placed behind the inferior vena cava into the oblique sinus and into the pericardium. Many groups do not place a pacing wire or use a pacing Swan Ganz catheter, but we have been very happy with routine pacing wires as this provides us with a margin of safety when managing the heart rate and is the same as for open surgery which makes ICU management more similar to other cases.
26. De-airing is undertaken and reperfusion of the heart for a period of time. Then the ventricular sump drain is removed and the suture line is tied down and bolstered with pledgeted CV4 Gore-Tex mattress sutures.
27. The pericardium is then loosely approximated with two sutures of 2-0 Ethibond (Ethicon, Inc., Somerville, NJ).

Figure 3. Robotic mitral valve procedure incisions.

28. Before removal, all robotic port sites are inspected for bleeding. Ports are then removed, CO₂ gas is evacuated, and both lungs are gradually reinflated. Gradual reinflation is an important part of the prevention of unilateral pulmonary edema. As part of this strategy we routinely cool the patient to 30 degrees Celcius to protect the lung.
29. Cardiopulmonary bypass is gradually weaned, rewarming is accomplished, and the patient is separated from bypass.
30. A completion echocardiogram is done at this point to assess the newly repaired valve.
31. If the repair is satisfactory, the robot is undocked, the pericardial retraction sutures are removed, and the diaphragm stitch is cut.
32. The endo balloon is removed followed by the venous cannula, the aterial perfusion cannula, and the distal limb perfusion cannula. The pursestrings are all tied down. If there is a concern for hemostasis of the artery or narrowing of the artery, clamps are applied and a more formal repair performed but this is not commonly required.
33. Once the cannulas are removed protamine is given for heparin reversal.
34. The right lung is then again deflated and re-exploration of the right chest is done with video thorascopy to ensure adequate hemostasis.
35. A 24 French Blake drain is placed through the right robotic arm in the right chest apex. All port sites are closed ending the procedure. (Figure 3)

OPERATIVE TECHNIQUE FOR TOTALLY ENDOSCOPIC ROBOTIC MITRAL VALVE REPLACEMENT

The technique used by the author is described below in general terms to present an overview of the operation. Specific pitfalls and troubleshooting are described later. The initial steps for mitral valve replacement are similar to those described above for repair. The steps only differ once the valve is encountered and are described as follows:

1. The anterior leaflet of the valve is often removed with a combination of robotic scissors and electrocautery. Care is taken to not damage the annulus or surrounding structures.

2. The valve is then sized and then a series of 2-0 Ethibond pledgeted sutures are placed robotically with a large robotic needle driver around the annulus with the pledgets on the ventricular side. These are kept in proper order by exteriorizing the sutures and placing them in a suture guide outside the patient in specific order.
3. At this point the assistant or the surgeon places the sutures through the valve ring, detaches the valve from the holder and lowers the valve in the patient within view of the robotic camera. In the case of a tissue valve, a “cinch” suture of 2-0 Prolene is used to temporarily guard against struts being caught by the sutures. This will later be removed.
4. The valve is then seated robotically while the assistant helps with tightening the sutures.
5. Once properly seated the sutures are tied down with Cor-Knot. In the case of a tissue valve, the “cinch” suture is cut and removed.
6. The valve is then static tested to evaluate for perivalvular leaks and rule out strut impingement.

PITFALLS AND TROUBLESHOOTING

In addition to the complications that may occur with any cardiac or conventional mitral valve procedure, there are a few complications related the robotic technique pertaining mainly to perioperative perfusion, ventilation or access establishment. Unlike its previous versions, the current daVinci Robotic System (XI) has not yet reported to cause any additional complications. Table 4 summarizes the complications that have been reported so far, along with tips to improve outcomes and for effective prevention and management of such complications.

Table 4. Pitfalls and troubleshooting

Pitfalls	Troubleshooting
I- Retrograde Perfusion related complications	
Embolic Strokes	Entire body vascular CT scanning to anticipate such complications pre-operatively. Modifying management plan accordingly.
Vena Caval Injury	
Dissections (Femoral and Aortic)	
Lower Limb Ischemia	Close monitoring of lower limbs' oxygen saturation and perfusing the femoral artery distally as needed using a shunt.
Right Ventricular Dysfunction and Air Embolism	Attention should be given to proper de-airing technique. Avoidance of the right 30 degree-up position. (risk of air embolism)
II- Ventilation related Complications	
Pulmonary Edema	Proper ventilation pressure (Low positive pressure during bypass is believed to be of benefit). Minimal lung deflation and perfusion times. Judicious blood product transfusions.
III- Surgical Technique and Iatrogenic Injuries	
Cross Clamp Injuries (The right pulmonary artery, left main coronary and atrium are at risk of injury by the posterior jaw)	Proper inspection of the clamp placement field.
Phrenic Nerve Injury (This injury can be caused by aggressive myocardial manipulation, cautery, or instruments)	Meticulous surgical technique and field anatomy identification are essential. Patients with poor pre-operative pulmonary function should be properly prepared for RVMP.

Eventually, it is imperative to emphasize that conventional sternotomy or at least videoscopic conversion are available options to consider when appropriate and confident RVMP cannot be conducted.

RESULTS AND DISCUSSION

Robotic mitral valve procedures have been shown to be as effective as conventional sternotomy mitral valve surgeries [4]. Similarly, the accuracy of repair or replacement relies largely on appropriate patient selection and surgical technique. Despite that its safety was put into question in a previous study, those findings failed to be generalized on the larger population of RMVP due to heterogeneity of the tested population and other factors [5]. This was followed by many successful reports from large institutions [6–10]. Mortality and stroke risks were found to be generally less than 1%, and a consensus has been reached regarding the most important factors for those results. Essentially, proper patient selection and preoperative assessment.

These concepts have been practiced in cardiac surgery, and in other surgical disciplines, since its birth in the past century. Other factors that warrants proper assessment are that concomitant cardiac pathologies could potentially affect the outcomes of RVMP, such as the case in concomitant aortic regurgitations. Regarding applicability, with the exception of mitral annular calcifications, RMVP could potentially be applied on any mitral pathology. Some of the obstacles against wide application include the additional complexity added to cardiac surgeries especially regarding perfusion technique and the need for optimal port placement. This also brings into picture the learning curve required for surgeons practicing such procedures. Ideally, a surgeon would require training in conventionally cardiac surgery, in addition to training in robotic surgery concepts. Such a long training curve takes into consideration the long training curve for cardiac surgeons. However, the commencement of this technique is much better than that of other minimally invasive surgical procedures, which are the standard of care today. Another issue regarding RMVP is cost-effectiveness. The increased cost of equipment and preoperative assessment still exceeds the benefit from shorter hospital stay and time to return to regular activity. However, it is believed that this would improve with time and experience to levels similar to that of conventional surgery [11].

COMBINED PROCEDURES

While mitral valve surgery remains the dominate use for robotic cardiac surgery, combined or concomitant procedures have not been well described. The first was done by Carpentier when he reported results of for patients treated with ring annuloplasty, one of which had a combined atrial septal defect closure [12]. Despite this initial combined procedure the use of robotics in cardiac surgery has mainly been limited to single procedure. However, more recent literature is showing that robotics can in fact be used for combined procedures. Certainly, concomitant procedures that are relatively easy to perform include: appendage closure, patent foramen ovals or atrial septal defect closure, tricuspid valve

repair, MAZE procedures, or tumor removal from the left atrium, right atrium, or left ventricle.

Hybrid CABG with PCI

Hybrid coronary revascularization combines the advantages of minimally invasive robotic coronary revascularization with percutaneous coronary stenting. One of the largest studies on the subject by Bonatti and colleges reported results on 226 patients who underwent hybrid coronary revascularization [13]. The majority (65.0%) of patients underwent a single bypass graft with surgery being done first in 70.8%, percutaneous intervention in 16.8% and a combined procedure in 12.4% of patients. Hospital mortality was 1.3% with an average length of stay of 6 days. Five-year survival was 92.9% and freedom from major adverse cardiac or cerebral event was 75.2%. The authors conclude that the hybrid technique provides a minimally traumatic cardiac intervention with shortened recovery time and outcomes comparable with standard cardiac surgery.

Hybrid strategies for patients with mitral disease and concomitant coronary artery disease include:

1. Changing to a traditional open coronary bypass and mitral procedure
2. Robotic mitral valve repair plus stents to a coronary (either before or after depending on the anatomy). We generally prefer after unless a critical lesion given need for anti-platelet agents with stent placement.
3. Robotic mitral valve repair and medical management of residual coronary disease (for example a moderate lesion in right coronary artery that is asymptomatic).

Although there have been anecdotal reports of combined robotic mitral repair and either robotic TECAB (totally endoscopic coronary artery bypass) or robotic MIDCAB (minimally invasive direct coronary artery bypass with robotic internal mammary artery harvest followed by hand-sewn anastomosis to the left anterior descending via a left anterior thoracotomy), the experience with this approach has been limited and very uncommon. We do not favor this approach given the added complexity and time required. Alternatively, we favor a hybrid approach when appropriate or conversion an open sternotomy strategy.

Other Minimally Invasive Procedures [14]

Similarly, minimally invasive mitral valve procedures are either to repair the native valve or to implant a new valve. These techniques have enabled the management of mitral valve lesions safely in high-risk patients for surgery. However, these techniques face many challenges and their true benefits are yet to be assessed.

For years, many surgeons have performed minimally invasive mitral surgery via several techniques. Both upper and lower mini-sternotomies have been used. Also a right “mini” thoracotomy or “port access” approaches have been popular. The advantage of such approaches over robotic endoscopic techniques is simplicity. The disadvantages are numerous including the need to spread the ribs (which often leads to more pain than even a sternotomy),

difficulty using long straight-shafted instruments with less degrees of freedom than those offered by the robotic instruments, the need for a larger incision to work through, and lack of an easily maneuverable 3D high definition camera to visualize the valve. Some surgeons do use a camera with a fixed arm but even this is not as versatile as the robotic option.

Another evolving option is trans-catheter mitral valve repair and replacement. Mitral valve lesions usually consists of multiple complex lesions. Based on this fact, surgical management is tailored to the complexity of the mitral valve pathology. In order to have outcomes comparable to surgery, transcatheter repair needs to take into consideration: appropriate selection of patients, designs for transcatheter mitral valves and stents, different anchoring methods and delivery modes, as well as valve materials. Any single design would inevitably affect other functioning parts of the mitral valve.

For trans-catheter mitral valve implantation, proper anchoring technique of the prosthesis is essential considering the imposed ventricular load. Anatomically, the mitral annulus is not perfectly circular, but rather saddle-shaped, and highly dynamic. The trigones of the mitral valve are continuous with the fibrous skeleton. Other areas of the annulus also can have variable degrees of compliance (annular calcification). The annulus is close to the coronary sinus and circumflex artery, imposing a potential for impingement. Other patients may also present with myxomatous degeneration with disjunction at the site of leaflet insertion.

Ideally, these prostheses must be multiplanar to avoid the risk of paravalvular leak. Perfecting the sealing area is crucial. Another issue is that the device must minimize interference with the outflow tract. Echocardiography and contrast-computed tomography techniques continue to be assessed in order to accurately predict this factor.

The placement of ventricular leads for cardiac resynchronization therapy is routinely done via an endovascular approach through the coronary sinus. When this is not possible or fails epicardial placement through a left sided mini-thoracotomy with robotic assistance has been described. This was first described in 2002 in Frankfurt, Germany by Kleine and colleges who reported left ventricular lead placement during biventricular defibrillator implantation [15]. This has shown to be a durable option for patients with favorable and stable pacing thresholds and lead impedance at 44 months [16].

Robotic cardiac surgery for the treatment of congenital heart defects, atrial fibrillation ablation procedures, myxoma resections, and aortic graft suturing have all be described in the literature [17]. However, these operations are limited to highly specialized centers and large case numbers have not been reported.

Due to the limited volume of studies and low number of patients the only procedures that meet criteria for randomized control trials are robotic mitral valve repair, hybrid coronary revascularization, and catheter ablation for atrial fibrillation.

ABSTRACT

Coronary artery bypass grafting (CABG) has been long been established as an effective method of restoring blood flow to the myocardium in the setting of advanced coronary artery disease. Grafting the left internal mammary artery (LIMA) to the left anterior descending coronary artery (LAD) improves long-term survival and multi-arterial grafting likely provides additional long-term benefits. Many patients do not receive the benefit of IMA revascularization due to the morbidity associated with CABG. Consequently, cardiac surgeons in the 1990s developed less invasive methods of myocardial revascularization from which spawned the development of robotic coronary artery bypass grafting procedures.

Minimally invasive direct coronary artery bypass grafting (MIDCAB) was independently described by Dr. Valavanur Subramanian and Dr. Federico Benetti in 1994 at the International Workshop on Arterial Conduits for Myocardial Revascularization and led to the presentation of a multi-center trial of 168 patients presented at the Annual Meeting of the American Heart Association in 1995. As MIDCAB was adopted by numerous surgeons, its challenges were identified including difficulty harvesting the entire length of the LIMA, limited access to the right internal mammary artery (RIMA), IMA rotation, target vessel identification, suturing through a small incision. Endoscopic techniques for IMA harvesting and anastomotic suturing were also developed, but proved to be very challenging and did not gain widespread adoption.

In the late 1990s, robotic technology became available, providing superior visualization of the entire thorax and improved intra-thoracic ergonomic motion for complex intra-thoracic procedures. This technology provided solutions for the challenges associated with endoscopic and limited access coronary artery bypass grafting by allowing ease of access to all intrathoracic regions from single sided ports allowing full

dissection of bilateral internal mammary arteries (BIMAs), target vessel identification, access to all regions of the myocardium and more facile anastomoses. Consequently, robotic assisted CABG became a reality and was adopted by a number of highly dedicated centers, where outcomes have been favorable. The procedure has evolved to the point where quadruple vessel CABG has become feasible. Procedures can be performed on the arrested and beating heart. This approach can be extended to approximately one-third of CABG patients when coronary anatomy is carefully assessed, usually in the context of a heart-team, and the treatment of each lesion is considered.

ARRESTED HEART TECAB

Totally endoscopic robotic coronary artery bypass (TECAB) grafting was first performed using cardiopulmonary bypass and cardioplegic arrest. This method provides several advantages over beating heart versions. Importantly, anastomoses are constructed on a still heart. With deflated lung and an empty heart, there is increased working space [1]. It is easier to manage technical challenges including bleeding, intramyocardial vessels, myocardial perforation, myocardial ischemia and hemodynamic instability.

ANESTHETIC CONSIDERATIONS

For the standard procedure, patients are positioned supine, elevating the left hemi-thorax 30 degrees. Defibrillator pads are placed out of the surgical area and optimally, leaving room for sternotomy in the event that conversion is required. Typically one pad is placed over the right pectoralis area and another posteriorly on the left. Lung isolation is usually achieved with a double lumen endotracheal tube, although a bronchial blocker can also be used. Standard invasive monitoring devices are utilized including arterial lines, central lines and transesophageal echocardiography. Myocardial protection can be augmented with a percutaneous retrograde coronary sinus cardioplegia catheter (Figure 1). A pressurized capnothorax is induced and may impact the hemodynamic status requiring interventions including fluid resuscitation, vasopressors and inotropes or a reduction in the insufflation pressure [2].

Figure 1. Anesthesia setup demonstrating the double lumen endotracheal tube, right internal jugular double stick for the retrograde coronary sinus cardioplegia catheter and central line with pulmonary artery catheter.

CARDIOPULMONARY BYPASS AND MYOCARDIAL PROTECTION

Cardiopulmonary bypass is achieved by peripheral cannulation. Preoperative computed tomographic angiography of the chest, abdomen and pelvis is performed to assess the vasculature [3]. A small incision is made typically over the right groin and the dissection is carried down to the anterior surface of the common femoral artery and vein. Double purse-string sutures are placed in each and after heparinization, both are cannulated using a modified Seldinger technique. A 6F sheath can be placed antegrade first after gaining access through a separate pursestring suture using a micropuncture kit for distal limb perfusion as a fairly large cannula is preferred when using an endoaortic occlusion balloon. Guidewire and cannula placement are confirmed with transesophageal echocardiography. Arterial cannulation is best performed with a perfusion cannula with a side arm through which an endoaortic occlusion balloon is passed over a guidewire into the aortic root. These maneuvers can be performed by the tableside surgeon, while the console surgeon is harvesting the internal mammary arteries.

Cardiopulmonary bypass is slowly initiated while being alert to high perfusion line pressure, which may signal a retrograde aortic dissection. Once stable flows have been established, the endoaortic occlusion balloon is inflated, its position confirmed between the sinotubular junction and the innominate artery with confirmation by transesophageal echocardiography. Cardioplegia is then administered to arrest the heart. A percutaneous pulmonary artery vent can assist in providing a dry operative field and a percutaneous retrograde coronary sinus catheter can be considered to augment myocardial protection.

SURGICAL PROCEDURE

Accurate port placement is an important consideration for a success procedure. The sternum is marked. Locations for the camera, right, and left arms of the robot as well as the subxiphoid port are marked (Figure 2). The camera port is placed first, lateral of the midpoint of the sternum where the chest begins to roll posteriorly, typically a centimeter (cm) or two posterior to the anterior axillary line. Caution must be undertaken when placing this port as it is typically done in a blind fashion. A pressurized capnothorax is induced at approximately 7 mmHg, watching that the hemodynamic profile of the patient remains stable. Under endoscopic vision, right and left arm ports are placed 7-8 cm cranial and caudal and 2 cm medial to the camera port.

After docking the robot, the IMAs are harvested. This is initiated by opening the endothoracic fascia and dissected away from the LIMA, working cranially and then caudally. Next, the IMA is gently teased from the loose connective tissue attachments to its venae comitantes. Low power cautery can be used to divide most branches while only the larger branches are double clipped and divided with Potts scissors. The LIMA is harvested from near its midpoint cranially to the phrenic nerve and then caudally to its bifurcation. After heparinization, it is clipped and divided distally. If bilateral IMAs are to be used, the retrosternal attachments are divided with electrocautery and long-tipped forceps. The RIMA is harvested first to avoid inadvertent injury to the LIMA after it is harvested as it could be out of the field of vision while harvesting the RIMA. The right pleural space is opened widely

creating a right pressurized capnothorax and maintaining the right lung out of the surgical field. The RIMA is harvested in the same manner as the LIMA. After the IMAs have been divided, hemostasis of the harvest site is ensured and an 8 mm assistant port is placed through the LIMA harvest site to bring additional supplies into and out of the thorax.

Figure 2. The endoscope is placed in the midpoint between the sternal notch and the tip of the xiphoid and laterally where the thumbs meet when placing the 5th fingers at the previous landmarks.

Figure 3. Right internal mammary artery harvest is carried out before the left using a skeletonized technique. Low power electrocautery is used to control most branches.

Cardiopulmonary bypass is established as described above. A stabilizer port is now placed by the tableside surgeon in the midclavicular line, about 2 cm caudal to the costal margin. Kelly forceps are used to dissect under the costal margin, scraping the posterior costal margin to avoid entering the peritoneum. Once the path is developed, the port is positioned and the third robotic arm is docked and the stabilizer is brought into the chest, ensuring that there are no external arm conflicts.

Figure 4. Target vessel identification is critical. The left anterior descending artery is seen coursing towards the apex of the left ventricle, usually appearing horizontal across the screen, or slightly upwards towards the left upper corner.

During the procedure, blood may collect in the pericardium and obscure the operative field. A small window is made in the pericardium posterior to the left phrenic nerve using long-tipped forceps and electrocautery. After arresting the heart as above, the pericardial fat pad is dissected from the lateral cranial aspect medially and then caudally towards the diaphragm. It is allowed to hang laterally which will assist in holding the pericardium out of the operative area. A pericardiotomy is then made in a similar fashion as the dissection of the fat pad, taking care to avoid the phrenic nerve and the left atrial appendage.

Identification of the target vessels is carried out by introducing the stabilizer and rotating the heart to see the appropriate coronary arteries. Typically, the LAD runs horizontally across the screen and even slightly upwards as one looks leftwards along the screen, whereas diagonal vessels tend to head towards the left bottom corner of the screen (Figure 4). Other vessels are identified by noting their position and characteristic features such as curves and branches. The vessels on the heart can be compared to the angiogram in the operating room, and potentially even viewed picture-in-picture on the robotic console. Grafting should obviously not be undertaken until one is confident that the intended target vessels have been identified.

Grafting is then undertaken. Typically, order of grafting proceeds first with right coronary artery targets followed by the left coronary artery vessels, working laterally towards the LAD. If sequential grafts are performed, usually the distal anastomosis is completed first.

The epicardium is dissected from the vessel using Potts scissors and a lancet blade is used to create an arteriotomy that is extended again using the Potts scissors. A small bulldog clamp is applied to the IMAs and the distal end is excised on an angle and extended. Flow through the graft is confirmed. Using a 7 cm 8-0 Pronova (Ethicon, Somerville, NJ) suture, the anastomosis begins at the 10 o'clock position of the target vessel driving the needle from inside to out and parking the needle in the epicardium. The second needle is passed through the graft from inside out and from outside in on the target, moving in a clockwise position

along the back wall of the anastomosis. After 3 bites, the graft is brought down by pulling up on both ends of the suture. Suturing continues along the back wall of the anastomosis in a similar fashion, coming around the heel to the 5 o'clock position and the needle is parked in the epicardium. The first needle is taken up and suturing now continues counterclockwise around the toe working from outside in on the graft and inside out on the coronary artery.

Patency of the heel and toe is confirmed by probing with a closed black diamond microforceps. After deairing, the suture ends are cut and pulled up and the anastomosis is inspected for loose bites, which can be tightened by using a needle as a nerve hook. An instrument tie completes the anastomosis and the suture ends are broken off with the microforceps (Figure 5). Hemostasis of the anastomosis is assessed by releasing the bulldog and patency is evaluated by visualization filling of the proximal and distal coronary artery, contraction of the area supplied by the graft and watching the myocardium turn pink. Graft flow is measured with a Doppler flow probe once the endoaortic occlusion balloon is released and contractions begin.

As the heart is reperfusing, all foreign materials are removed from the chest with help from the tableside assistant. Vasodilators can be sprayed on the grafts and anastomoses by the tableside assistant and guidance from the console surgeon. Graft lie and length is assessed while the patient is weaned from cardiopulmonary bypass. Transesophageal echocardiography is used to confirm appropriate wall motion and the patient is decannulated. Protamine is administered and hemostasis of the surgical sites is confirmed with careful attention to the mammary artery beds and each port site. After the robot is undocked, port sites are again inspected using the robotic endoscope and the ports are packed with a topical hemostatic agent. The lungs should be reinflated under direct visualization and the port sites closed. Long-acting local anesthetic is infiltrated around the port sites and intercostal blocks can be placed.

Figure 5. Suturing the left internal mammary artery to an obtuse marginal branch is very comfortable with the robot, which provides excellent magnification and visualization.

Multi-arterial coronary artery grafting can be undertaken using a combination of bilateral internal mammary artery, radial artery and saphenous vein grafts in single, sequential and Y-graft configurations. Typically, Y-grafts are constructed in the thorax prior to opening the pericardium. The endostabilizer can be used to provide a stable platform to complete the Y anastomosis. Vein grafts can be attached to the left subclavian artery [4] and brought through the chest wall. These techniques have allowed for triple [5] and even quadruple [6] coronary artery bypass procedures.

BEATING HEART TECAB – SUTURE TECHNIQUE

TECAB can also be performed on the beating heart. With the heart full and beating and without the safety net of cardiopulmonary bypass, additional considerations are important. Positive airway pressure on the deflated lung may enhance oxygenation. An experienced anesthesiologist is important to assist in managing hemodynamic derangements from a pressurized capnotherax and clear communication between the surgeon and anesthesiologist are important as changes in physiology and ventilation parameters can lead to cardiac trauma. Transthoracic echocardiography is important to monitor the heart during the procedure. Careful administration of pharmacologic support can minimize changes in contractility and heart rate, which can make suturing on the beating heart more challenging. Lidocaine is infused intravenously during the procedure to stabilize ventricular arrhythmias.

Patient positioning and port placement is the same as arrested heart TECAB. IMAs are harvested as required, preferably in a skeletonized fashion, but the graft should be left attached to the chest wall in several locations. With the endoscope looking down, the pericardial fat pad is resected and the pericardium opened. Short bursts of cautery should be used to minimize the risk of ventricular arrhythmias.

Once the target vessel is identified, the endostabilizer is introduced and heparin is administered to maintain an activated clotting time greater than 300 seconds. Papaverine is sprayed onto the graft. All devices for completing the anastomosis are now brought into the operative field and secured, including two locking silastic and a soft-tipped bulldogs. After placing two clips on the distal IMA and the bulldog proximally, it is partially divided and spatulated. A 7-0 double-armed Pronova suture is placed at the heel and toe and the IMA transection is completed. Once the endostabilizer is positioned, the epicardium is dissected away with a robotic beaver knife and the edges can be clipped to the adjacent epicardium to aid with exposure. A clip is used to hold the graft near the target vessel. Locking silastic loops are now secured proximally and distally around the target vessel and secured. An arteriotomy is made with an endoscopic lancet knife and extended approximately 4 mm as appropriate with Potts scissors. The Pronova sutures are brought through the heel and toe of the target vessel, the graft is lowered into position and three instrument throws are placed. Completion of the anastomosis is carried out along the back wall from heel to toe, placing sutures inside out in the target and outside in on the graft. Once the toe is reached the suture is tied to one arm of the toe stitch. Switching back to the heel, the remaining suture is brought towards the toe, suturing outside in on the graft and inside out on the vessel up to the midpoint of the front wall of the anastomosis. Finally, the remaining arm is brought counterclockwise along the front wall of the anastomosis to meet the heel stitch at the midpoint. Once the anastomosis is

tied, hemostasis is confirmed and graft flow is assessed with transit time Doppler [7,8]. Additional grafts are completed in a similar fashion and the operation completed as described above for arrested heart TECAB.

(B)

(C)

Figure 6. (A) LIMA graft is loaded on the anastomotic device. The anvil is inserted into the target vessel parallel to its long axis. (B) After insertion to the tissue stop, the tableside surgeon fires the anastomotic device. (C) A completed anastomosis with a plump hood and no bleeding. (Courtesy of Dr. Husam Balkhy, The University of Chicago).

BEATING HEART TECAB – USING AN ANASTOMOTIC DEVICE

Anastomotic connectors have been developed to facilitate reproducible anastomoses [9]. Although these have not been taken up for routine CABG surgery via sternotomy, they have advantages in TECAB and can potentially simplify the operation. Setup for the procedure is similar as for sutured beating heart TECAB procedures. A skeletonized IMA is preferred especially if a Y-graft is to be constructed and simplifies intrathoracic manipulation of the graft. Once the IMAs are harvested, the stabilizer port is placed and the 4th arm is docked. The coronary artery target is stabilized with the robotic stabilizer and the coronary artery is prepared. Once the epicardium is dissected, a silastic snare is placed around the artery and a polytetrafluoroethylene CV8 (Gore Medical, Flagstaff, AZ) horizontal mattress adventitial stitch is taken a few millimeters proximal to the anastomotic site. Heparin is administered to achieve a target activated clotting time of 300 – 350 seconds. Partial transection of the IMA provides access to insert a small catheter to instill papaverine.

The Flex A (Dextera Surgical, Inc., Redwood City, CA) device is positioned through a 15 mm port in the second left intercostal space in the midclavicular line with the cartridge and anvil gently approximated. All robotic instruments are removed from ports prior to inserting the device as the reduction of capnothorax may allow the heart and lung to move towards the chest wall, which could cause injury. While grasping the one of the heel tabs of the Flex A device with a DeBakey forceps or heavy needle driver, the Flex A device cables are aligned with anvil facing the heart and the device is then rotated counter-clockwise towards the sternum with the tip angled towards the camera port. The IMA graft is rotated and aligned with the anastomotic device and is spatulated for a length of approximately 8-9 mm. Grasping the adventitia on either side of the heel, the graft is loaded onto the heel clip of the device and the tableside surgeon activates the piercer. To ensure an appropriate hood size and to protect the graft during the arteriotomy, the graft shield is then deployed onto the hood of the graft. Subsequently, the graft edges are draped over the device and the right-wing guard is lowered by the tableside surgeon who then removes the piercer and deploys the left-wing guard. Once the stabilizer is introduced and the target vessel is again exposed and stabilized, a 1 mm arteriotomy is made in the target vessel at the location of the previously placed stitch. While holding the device by a tab, the anvil is very carefully inserted into the target vessel at a 45-degree angle, and then orienting the anvil parallel to the target. It is critical that the anvil is confirmed to be intraluminal (Figure 6a). Once the device has been advanced to the tissue stop, the tableside surgeon fires the connector (Figure 6b). Care must be taken to avoid disrupting the anastomosis while removing the device. The anvil stitch is then tied and the anastomosis is inspected (Figure 6c). If there are signs of coronary ischemia, a shut can be used. Additional grafts are then constructed. Y-grafts can be completed in a similar fashion. Side-to-side anastomoses are typically completed after the distal anastomoses to avoid damaging the more proximal anastomosis while manipulating the conduit for the distal anastomosis. Completion of the procedure is carried out as with other TECAB operations described above [10].

ROBOTIC-ASSISTED MIDCAB

Many surgeons find the leap from open to endoscopic robotic coronary surgery very daunting. One method to bridge this gap and an excellent sternal sparing procedure that can be simpler is the robotic-assisted minimally invasive direct coronary artery bypass (RA-MIDCAB). This procedure offers the patients the benefits of minimally invasive coronary surgery, while avoiding the complexities of completing an intrathoracic anastomosis yet overcomes many of the limitations of a conventional MIDCAB operation. In the standard MIDCAB procedure, it can be challenging to harvest the entire length of the LIMA and is very challenging to take down the RIMA, leading to concerns regarding graft length. With robotic assistance, BIMAs can be harvesting in their entirety and the anastomosis is completed with standard hand-sewn beating heart techniques through a very small left thoracotomy.

Preoperative work-up anesthetic considerations and patient positioning are similar to other robotic coronary procedures. At the crux of a successful RA-MIDCAB is the perfect positioning of the endoscopic port, as this incision will be extended to complete the anastomosis. Consequently, it is important to mark the location of the midline of the sternum, and the locations of the LIMA and diaphragm. Plain posteroanterior and lateral chest x-rays are valuable in determining the optimal location of the endoscope port. First, the midpoint of longitudinal axis of the sternum is located. Second, the medial-lateral orientation of the endoscope port is gained by noting how lateral the apex of the heart is on the posteroanterior x-ray and matching its position externally on the left hemithorax. Finally, consideration is placed on whether the anticipated anastomotic location on the LAD is more proximal or distal and the port is moved one interspace more cranially or caudally as required.

Once the endoscope port is positioned and a capnothorax is induced, right and left arm ports are installed and can be lifted to enhance intrathoracic working space. One or both IMAs are now harvested as above. It is helpful to make a small pericardial window posterior to the left phrenic nerve to avoid buildup of fluid that can impede visualization of the anastomosis. After the pericardial fat pad is retracted laterally the pericardium is opened widely, but not beyond the apex.

One of the major benefits of RA-MIDCAB over tradition MIDCAB is localization of the LAD and the ideal location for the anastomosis. Inspection of the LAD is carried out and the ideal location for the anastomosis is marked with several hemoclips so that if one falls off, the preferred location of the anastomosis can still be identified. Orientation of the LIMA is maintained by placing a stitch in the adventitia and epicardium or pericardium near the target area.

After the robot is undocked, the anastomotic site is identified through the endoscope port site and enlarged in an appropriate direction. A soft tissue retractor is position, taking care to avoid trapping the LIMA graft. The suction tubing of the stabilizer is brought from the minithoracotomy through the inferior robotic port and the stabilizer is placed in the incision and is connected to the stabilizer pole which is inserted through the inferior robotic port. Positioning of the heart can be enhanced with tractions sutures on the pericardium. A standard hand-sewn anastomosis is now undertaken after placing a silastic loop around the target vessel

HYBRID REVASCULARIZATION

Another aspect in the evolution of TECAB and robotic coronary surgery is the development of hybrid procedures. Hybrid coronary revascularization (HCR) is the combination of coronary artery bypass with the use robotic assistance in addition to percutaneous coronary intervention (PCI) to treat remaining diseased coronary vessels. Approaches using the combination of TECAB and PCI as well as robotic-assisted CABG and PCI are in practice today. This can include treating one or more vessels endoscopically and either followed by, or preceded by PCI. In some institutions with access to hybrid operating rooms, PCI is able to immediately follow bypass during the same operation. This offers intervention to all of the diseased vessels in a single setting and also allows immediate evaluation of the LIMA-LAD patency. Other programs are performing surgery prior to PCI; whether PCI was followed within the same week or was months later tended to vary. Many practices prefer surgery before PCI as patients are not yet on dual antiplatelet therapy [11]. The remaining option is to perform PCI prior to surgery, a situation preferred if the culprit lesion or vessel with most severe stenosis would be approached via PCI.

Drug-eluting stents (DES) were most commonly used. A meta-analysis reports DES were used nearly 90% of the time. Cases in which DES were not used, utilized bare metal stents, angioplasty and thrombo-aspiration [12].

Outcomes of hybrid revascularization techniques prove that these procedures can accomplish good results with low morbidity and mortality. Bonaros et al reported a 0% mortality, 3% rate of myocardial infarction (MI), and a less than 1% rate of stroke. This study found no difference regarding the sequence of the interventions, whether PCI was performed before, during, or after the bypass [13]. Bonatti and colleagues also observed a 0% mortality rate in a study including 140 hybrid procedures. Follow-up at 5 years revealed a freedom from bypass re-intervention rate of 97.3% and a freedom from PCI re-intervention rate of 85.8% [14]. A meta-analysis by Harskamp et al did not identify a difference in the rates of death, MI, stroke in the short term post-op period, but did note higher rates of repeat revascularization in the hybrid group compared to the conventional CABG group. This study was also able to show that HCR was associated with less frequent blood transfusions, shorter hospital length of stay, and a faster return to work [15].

In addition to endoscopic bypass of LAD to LIMA, hybrid approaches may also include multi-vessel bypass to accompany PCI. After analysis of hybrid procedures involving single vessel versus multi-vessel bypass, outcomes were no different. This finding, in addition to understanding that coronary bypass is superior to PCI alone, emphasizes that LAD-LIMA bypass is the key component to successful outcomes. Taking this into consideration, determining the best approach to revascularization of the remaining diseased vessels must be established. As stent technology improves, compelling evidence exists supporting DES being superior to vein grafts as they have been shown to have patency rates higher than that of vein grafts. This argues that a single vessel TECAB in combination with PCI may generate best long-term results.

When comparing hybrid techniques to conventional approaches, it is important to keep in mind that patient risk factors and comorbidities are known to be greater in those undergoing open procedures. With appropriate patient selection, hybrid coronary revascularization offers

the gold standard of bypass to the LAD with a new approach to the treatment of multi-vessel disease.

LEARNING CURVE

As with any new surgical procedure, TECAB is a complex operation with a steep learning curve and challenges along the way. Overcoming the learning curve requires direction. Purposeful steps should be taken to ensure safe and successful integration of robotics into a cardiac surgery practice. Several studies have shown that it is feasible to obtain outcomes comparable to that of traditional open bypass procedures or other minimally invasive techniques. Many have compared their outcomes over time and have shown that with the proper preparation and patient selection, TECAB can be successfully performed and provide an equally efficacious surgical option.

To successfully initiate a robotics program, many have adopted a stepwise approach: starting with LIMA harvesting, then moving to pericardiotomy, and eventually adding anastomosis to LAD. Once successful single vessel TECAB has been accomplished, more complex procedures can be performed, including bilateral internal thoracic artery harvest, hybrid coronary revascularization procedures, and multi-vessel TECAB.

As previously stated, implementation of robotic assistance generally starts with harvesting of the LIMA. This can be done with complete or incomplete skeletonization of the graft. Overcoming the learning curve for this can be accomplished after approximately twenty cases [16, 17, 18]. Operative times shorten, conversion rates decrease and blood transfusions decrease once this threshold is reached. Many programs have chosen to routinely perform robotic assisted coronary artery bypass by harvesting the LIMA endoscopically and performing the remainder of the case via mini-thoracotomy. This has been proven advantageous to increase conduit length while also using a technique that limits trauma to the chest wall, thus causing less post-operative pain [19]. Surgeons then move on to perform subsequent portions of the operation robotically with planned conversions at various steps in the operation or after a various amount of time has passed, as it has been proven operative time plays an important role in clinical outcomes.

A critical factor in developing a successful endoscopic cardiac program is proper patient selection. Exclusion criteria vary, but typically include patients with a low ejection fraction (<30%), distal coronary target vessel smaller than 1.5 mm in diameter, a history of left lung trauma, previous left lung surgery or even sternotomy, patients requiring emergency bypass and patients with significant lung disease with an inability to tolerate single lung ventilation. Others simply exclude patients with any significant medical comorbidities that may deem the patient to have less biological reserve [18]. Rates of successful TECAB completion have proven higher with a strict criterion for patient selection, leading to lower morbidity and mortality.

Although many of these potentially limiting factors can be determined pre-operatively, other factors that reduce success rates are not found until entry into the thoracic cavity. It is important to recognize these limitations and understand when to convert to an alternative minimally invasive or open technique to complete the operation. While no absolute criteria

exist for operative conversion of the procedure, many factors have proven to portend worse outcomes if encountered.

One anatomic limitation includes dense pleural adhesions that inhibit viewing the anatomy and limiting working space in a closed chest. Another limiting factor based on the patient's anatomy is an intramuscular target vessel that was not identified on preoperative imaging. The tenuous dissection is such that it is unlikely to be performed successfully endoscopically, and an approach with direct visualization and higher familiarity should be chosen. Another reason to convert to a different approach specific to this operation include injury to the graft during LIMA dissection. If the graft is unable to be salvaged, a separate graft needs to be determined and the procedure should be converted to a technique that is amenable to usage of other types of conduits. If the LIMA is able to be safely dissected and harvested, but the anastomosis is unsatisfactory, many centers are suggesting conversion at this time to ensure adequate patency upon conclusion of the operation, rather than endoscopic revision. This is undoubtedly surgeon and case dependent.

Also, it is understood with any new approach to an operation that times may be longer than standard approaches. This is no different when performing a TECAB. Although operative times continue to decrease, TECAB times remain longer than most open/minimally invasive bypass operations performed without the use of endoscopy. Given the benefits of TECAB, longer operative times are an acceptable outcome; however, this should be limited. Several studies have shown as operative time increases, CPB time increases, as does single lung ventilation, causing longer ventilator times post-operatively, longer intensive care unit (ICU) and hospital stays, as well as increased morbidity and mortality. It is important to have a threshold to convert from an endoscopic technique when that threshold is met [18]. Studies have shown that worse outcomes occur once eight hours is exceeded, thus the procedure should be converted when nearing this point [20].

Other factors that Bonatti et al. studied and determined to positively impact the learning curve included the use of a consistent operative team, using fibrin glue at the anastomosis, and adding a fourth endoscopic port for a tableside surgeon to assist. Operative times, which some use to measure overcoming the learning curve, were found to improve with each additional modification [17, 18, 21].

OUTCOMES

The use of robotics in coronary bypass continues to evolve and improve. Utility ranges from harvesting the LIMA robotically before subsequently performing the anastomosis and completing the operation through a non-robotic technique, to a totally endoscopic coronary artery bypass (TECAB), performed either on or off pump, as well as with single or multiple grafts. Feasibility alone has been proven for quite some time now, dating back to the first reported TECAB twenty years ago [22]. However, safety and efficacy continue to be closely monitored to ensure adequate outcomes.

Intra-operative conversion rates continue to decline, and many recent studies have shown a conversion rate of less than 10% [23,24]. Several reasons are attributed to the need to convert to an open procedure. LIMA injuries typically account for 2% or less, which is around 1% in an open bypass technique. Poor graft flow after anastomosis and bleeding at the

anastomosis site are also reasons endoscopic cases require conversion, although typically only 1-2% of the time [24]. Other conversions can be attributed to adhesions precluding visualization, patient intolerance, or immediate graft dysfunction being identified. It has been noted that the need for return to the operating room for immediate complication tends to occur 1-2% of the time as well, but this seems comparable to conventional approaches to coronary bypass and is generally secondary to bleeding [1]. Cardiopulmonary bypass time has been reported to average between 110-120 minutes for TECAB, compared to conventional cases, which average just over half that time. Similarly, cross-clamp times are nearly twice as long in some reports for robotic procedures [25].

Post-operative results prove TECAB to be a safe procedure with satisfactory results. Rates of myocardial infarction, stroke and mortality have also been evaluated, which reveal no difference in the two groups [23]. Argenziano et al. reported an MI rate of 1.2% and a mortality rate of 0% in a prospective study evaluating outcomes of single-vessel TECAB [24]. Bonatti et al. observed a 0.7% mortality rate in a study of over 400 TECAB patients. This study also reported a significantly lower heart failure rate (1.2% in the TECAB group, and 8.6% in the conventional open group) and a lower new onset atrial fibrillation rate (1.2% vs. 16.8%) [26]. Length of stay in the ICU and in the hospital are comparable to conventional approaches when evaluated in a propensity score match comparison [25]. However, a prospective study by Leyvi et al. showed that discharge to an acute care facility was significantly lower in the TECAB group when compared to the conventional group (16.0% vs. 25.83%, $p=0.008$) [27].

Graft patency rates have consistently been described to be 95% or greater, even after three-year follow-up. In 2015, Yang et al. reported graft patency of 240 consecutive patients who underwent off-pump coronary bypass with robotic assistance, 100 TECAB and 140 mini-thoracotomy coronary artery bypass (MINICAB). Graft patency was evaluated with either coronary angiography or computed tomographic angiography. The IMA graft patency was 97.1% in TECAB and 96.4% in the MINICAB group over three years post-operatively [1]. In a study by Argenziano et al, three-month angiography was performed on 76 patients, which identified graft occlusion in two cases and significant anastomotic stenosis in four cases, in addition to one case that required re-intervention on post-operative day one for graft occlusion. Of the six that were observed at three month follow-up, only one patient was symptomatic and required re-intervention, yielding a high freedom from graft failure rate [24]. It has been reported that there is no increased rate of re-do operations or need for percutaneous interventions of those undergoing TECAB [1].

Although CPB and total operative time remains longer than conventional CABG approaches, TECAB has proven a safe and efficacious operation. As surgeons continue to employ this technique, proficiency continues to improve. Prospective randomized trials are currently not available for comparison between techniques and may not ever be. Current studies that attempt to compare all patients undergoing CABG are including patients who tend to have more co-morbidities and higher rates of urgently performed operations. The literature that does exist for TECAB proves that with proper patient selection, this is an operation with great outcomes.

Chapter 249

ROBOTIC APPROACHES FOR RECTAL CANCER

Kevin T. Behm and David W. Larson*

Division of Colon and Rectal Surgery, Mayo Clinic, Rochester, MN, US

INTRODUCTION

Minimally invasive techniques have revolutionized the field of colon and rectal surgery since their inception in 1991 by Jacobs et al. [1]. Through the years multiple landmark randomized controlled clinical trials including the COST, COLOR, CLASICC, and Barcelona study not only demonstrated equivalent oncologic outcomes, but also proved the superiority of laparoscopic surgery over standard open technique with respect to short term outcomes [2-10]. Despite this data laparoscopic techniques have been challenged by slow adoption. As of 2011 only 42.2% of colon resections are being performed laparoscopically at academic centers and conversion rates remain high at 15.8% [11]. While diffusion of laparoscopic colectomy for cancer continues unabated, total mesorectal excision (TME) for rectal cancer remains controversial.

Major randomized control trials including the MRC CLASSIC, COREAN, and COLOR II have compared open to laparoscopic TME (LTME). Concerns were raised initially in the CLASSIC trial with high rates of circumferential radial margin positivity (CRM+) at 12% and high rates of conversion to open surgery at 34%. While the COLOR II trial showed significantly lower rates of positive CRM+ (5.0%) rates of conversion remained high (16%) confirming the technical expertise required for LTME. To date however, these trials have demonstrated no difference in oncologic outcomes with improved short-term outcomes for those with rectal cancer [6-8, 12-14].

In the US, Australia, and New Zealand controversy over LTME remained. In response to these concerns two large multicenter, randomized, non-inferiority trials (ACOSOG Z6051 and ALaCaRT) were established to determine whether LTME was non-inferior to OTME for the management of locally advanced rectal cancer. Successful resection was determined in each trial by a composite of three surrogates and included circumferential radial margin (CRM) greater than 1 mm/ $\text{CRM} \geq 1 \text{ mm}$, distal margin without tumor/ distal resection margin

* Corresponding Author's Email: Larson.David2@mayo.edu.

≥ 1 mm, and completeness of TME respectively. The ACOSOG trial demonstrated successful resection in 81.7% of laparoscopic resection cases and 86.9% of open resection cases which did not support noninferiority (difference, -5.3% ; 1-sided 95% CI, -10.8% to ∞ ; P for noninferiority = .41) [15]. Conversion rate was 11.3%. The ALaCaRT trial reported similar results with successful resection in 82% of the laparoscopic group and 89% in the open surgery group (risk difference of -7.0% [95% CI, -12.4% to ∞]; P = .38 for noninferiority). Conversion rate from laparoscopic to open surgery was 9% [16]. Both studies are examples of excellent quality amongst both surgical arms, but the findings did not provide sufficient evidence for the routine use of laparoscopic surgery for the treatment of rectal cancer until long term outcomes could be confirmed. At present the oncologic impact of these preselected surrogates for successful resection has not yet been determined.

Beyond the controversy of current literature and research are the operative issue of pelvic surgery. The challenges of pelvic dissection include difficult operating angles, narrow working space, and proximity to surrounding structures. The robotic surgical platform has significant technical advantages over traditional open or laparoscopic surgery including a stable surgeon controlled 3D image, finer dissection with articulated instruments, the addition of a third surgeon controlled arm, and dramatically improved surgeon ergonomics. These advantages have the potential to improve multiple aspects of care. Current and future research will be needed to identify the impacts to learning curve, complication rates, conversion, and oncological outcomes. This chapter will focus on operative technique and outcomes from current published work comparing robotic approaches to lower anterior resection and abdominoperineal resection for the management of rectal cancer using the da Vinci robotic system (Intuitive Surgical Inc., Sunnyvale, CA, USA).

INDICATIONS FOR ROBOTIC APPROACH

The robotic platform is used for the treatment of both benign and malignant diseases encompassing the entire field of colon and rectal surgery. Robotic colon and rectal procedures continue to increase annually as surgeons expand this MIS practice. Our chapter's focus will be on the use of robotics in the pelvis, as this represents the most technically demanding application of the platform and the area of greatest research. Despite the significant increase in the number of robotic colon and rectal procedures, quality data remains limited. The available data consists mostly of single-center experiences and small prospective studies. Despite limited data, the findings have consistently shown the safety and feasibility of robotic approaches across a breadth of procedures [17-22]. As a critical adjunct to the technical aspects of surgery we acknowledge and recommend care process models including enhanced recovery pathway (ERP) principles within a robotic surgical practice. Enhanced recovery pathways include multi-modal pre-, intra-, and post-operative elements in an attempt to operate in a physiologically normal state, optimize post-operative pain control, manage post-operative nausea, limit fluids, and allow for institution of a general diet [23-24]. Together these techniques and care processes will help to shape the future of pelvic surgery.

OPERATIVE TECHNIQUE

Initial Approach

The ultimate docking position of the robot is dependent upon the surgical approach being undertaken. For a patient undergoing rectal resection, a modified lithotomy position is chosen to provide access to the perineum. Abdominal access can be obtained by a variety of methods. We prefer the use of a modified open technique, utilizing an Optiview trocar (Ethicon Endo-Surgery, Inc., Summerville, NJ) placed under direct visualization a few centimeters to the right of the midline just superior to the umbilicus. The Optiview trocar has particular benefit in an obese patient in which a traditional open technique is difficult secondary to poor visualization. Ideally the camera port should be 15-20 cm from the target anatomy. Pneumoperitoneum is established, and the abdomen is explored to ensure there is no evidence of metastatic disease.

The additional trocar sites are then measured out and marked ensuring 6-8 cm between each robotic cannula to avoid external or internal collisions. We generally place two additional 8 mm robotic trocars, one 12 mm robotic trocar, [Figure 1] and one assist port. The 8 mm robotic trocars are placed in the left lower quadrant, approximately at the mid-clavicular line and in the left lateral abdomen cranial to the anterior superior iliac spine (Arms 1 and 2, respectively). The 12-mm robotic stapler port is placed in the right lower quadrant in the mid-clavicular line (Arm 4). The 5-mm assist port is placed in the right upper quadrant. This is positioned to allow the assistant to avoid colliding with the robotic arms while allowing appropriate access to the deep pelvis. This port is a 5 mm Airseal port that utilizes Airseal System (ConMed, Utica, NY) to allow for stable pneumoperitoneum and continuous smoke evacuation for improved visualization during deep pelvic dissection.

Precise trocar placement is critical when performing robotic proctectomy. If inappropriate trocar sites are selected the boney aspects of the pelvic sidewall and sacral promontory can create significant impedance to safe surgical dissection. Trocars placed too far cephalad in a patient with a long torso will make the presacral dissection towards the pelvic floor difficult secondary to reach. Trocars placed too far laterally (particularly in a male patient) will make the low pelvic dissection difficult secondary to collisions with the lateral pelvic sidewall.

With the trocars in appropriate position the patient is placed in steep Trendelenburg allowing the small bowel to fall out of the pelvis. The robot is then docked over the left hemiabdomen aligning the targeting icon directly over Arm 3. With the arms docked the 30-degree camera is placed in Arm 3 and the targeting technology is utilized to align the robotic arms for pelvic dissection. The Small Grappler is placed in Arm 1, the fenestrated bipolar forceps in Arm 2, and the monopolar-curved scissors in Arm 4.

In addition, the Xi platform can be paired with the Trumpf Medical TruSystem 7000dV table (Trumpf Medical, Saalfeld, Germany) allowing the surgeon to use Table Motion technology. This innovation allows the patient to be repositioned throughout the operation without undocking the robotic arms. This provides further flexibility when performing multiquadrant operations or when operating on patients with severe visceral obesity.

Figure 1. Trocar positions for pelvic dissection.

OPERATIVE STEPS

Step 1 – Exposure

Using Arm 1, the rectosigmoid junction or its mesentery is grasped and the rectum is placed on tension proximally, pulling it out of the pelvis. Alternatively, an assistant may grasp this area, allowing Arm 1 to grasp more distally on the rectum to provide additional traction, placing the rectosigmoid mesocolon and mesorectum on tension. It is critical that the upper rectum be elevated in such a way as to stretch the peritoneum overlying the right pelvic gutter, as well as the superior rectal artery to help separate the vessels from the sacral promontory. In a female patient, it may be necessary to suspend the uterus to obtain an unobstructed view of the pelvis. We place a suture trans-abdominally around the round ligaments to suspend the uterus anteriorly.

Step 2 – Control of the Inferior Mesenteric Artery (IMA) and Inferior Mesenteric Vein (IMV)

The monopolar shears are utilized to incise the peritoneum along the right side of the rectum, caudal to the sacral promontory. This technique exposes and opens the presacral space [Figure 2A/B]. Dissection is carried cephalad along the posterior aspect of the mesorectum towards the IMA [Figure 3A], taking care not to breach the fascia propria of the rectum and avoiding injury to the superior hypogastric nerves. Injury to the nervous structures

around the IMA may result in retrograde ejaculation and/or bladder dysfunction. As one dissects directly below the superior rectal artery and above the retroperitoneal fascial planes, the left ureter and gonadal vessels should be identified just above the pelvic brim. As the dissection continues in this plane, the vessel is elevated from the retroperitoneum and the ureter and gonadal vessels can be easily swept bluntly posteriorly to maintain their position within the retroperitoneum, posterior and lateral to the IMA [Figure 3B].

Dissection is carried along the IMA until the origin is reached in order to perform a complete D3 lymphadenectomy. The IMA is skeletonized with the monopolar shears, ligated utilizing three da Vinci robotic clips (two proximal and one distal), and divided sharply [Figure 4A/B/C]. The decision to ligate the IMA proximal or distal to the left colic artery is determined by the need for colonic length. If a low pelvic anastomosis is required the IMA is divided proximal to the left colic artery, while a more proximal anastomosis will allow preservation of the left colic branch.

Once the IMA is ligated and divided the colonic mesentery can now be elevated off the retroperitoneum proximally and laterally. The extent of dissection extends to the inferior border of the pancreas and laterally overlying Gerota's fascia. The cut edge of the colonic mesentery can continue to be transected superiorly, lateral to the duodenum and medial to IMV. The IMV is traced proximal to the inferior border of the pancreas where it is isolated and divided with the da Vinci Vessel Sealer.

Figure 2A/B. An unobstructed view of the pelvis is obtained. The rectum is retracted cephalad and to the left using Arm 1. The rectum must be elevated to stretch the peritoneum and raise the superior rectal artery anteriorly to separate the vessels from the sacral promontory. Electrocautery is then used to incise the peritoneum along the right side of the rectum, caudal to the sacral promontory.

Figure 3A/B. Identifying and isolating the inferior mesenteric artery - dissection is carried cephalad along the posterior aspect of the mesorectum towards the IMA. Arm 2 (LLQ) is placed posterior to the vascular bundle and mesorectum and retracted anteriorly. The assistant may place counter traction using either a laparoscopic grasper or suction device to aid the dissection. The vessel is elevated from the retroperitoneum and the gonadal vessels and ureter should be identified within the retroperitoneum, just above the pelvic brim, posterior and lateral to the IMA.

Our typical approach at this point includes taking the colonic mesentery just proximal to the pedicle of the IMA to the edge of the junction of the sigmoid/descending colon. This allows for complete vascular isolation of the target anatomy, and provides an estimate as to the proximal area for anastomosis. Once the mesentery has been divided we do not divide the bowel as it provides a fantastic opportunity for retraction during the pelvic dissection.

Step 3 – Rectal Dissection

The proximal rectum is grasped with the Small Grasper utilizing Arm 1 and the rectum is retracted out of the pelvis. Arm 2 is placed posterior to the mesorectum and elevated anteriorly opening the presacral plane while the monopolar shears in arm 3 perform the sharp dissection. This dissection is carried as far to the left pelvic sidewall as possible to decrease the amount of dissection necessary from the patients left side [Figure 5A/B]. The posterior dissection is continued distally, including the lateral stalks, which are taken with monopolar cautery. If a middle rectal vessel is present within the lateral stalks and not controlled with

cautery, this may be controlled with either bipolar or the robotic vessel sealer. The instrumentation in Arms 4 and 2 may be exchanged in order to complete the dissection along the left side of the rectum. Dissection that is too lateral in the region of the lateral stalks places the *nervi erigentes* at risk for injury, which can lead to erectile dysfunction.

Figure 4 A/B/C. Ligation of the IMA is shown. The pedicle is completely cleared utilizing the monopolar shears. Prior to ligation, this retroperitoneal plane should be developed such that the empty space between the IMA and left colic artery in the colonic mesentery is visualized. Arm 1 continues to retract the rectum out of the pelvis and places the IMA on a near vertical orientation. Arm 2 can be used to grasp the peritoneum overlying the vessel (as shown), or the vessel itself, distal to the transection point. The IMA is ligated utilizing three da Vinci® robotic clips (two proximal and one distal), and divided sharply.

Figure 5A/B. We typically start the presacral dissection along the posterior, right side and proceed caudally – Arm 1 maintains traction on the rectum in a cephalad direction, out of the pelvis, Arm 2 retracts the mesorectum toward the patient's left side and Arm 4 is used to perform the dissection. This dissection is carried as far to the left pelvic sidewall as possible to decrease the amount of dissection necessary from the patients left side.

The anterior dissection is then undertaken. Initially Arm 1 is used to pull the rectum out of the pelvis in a posterior vector to provide proper tension on the anterior structures. The assistant aids the dissection by placing a suction device or grasper anterior at the level of the seminal vesicle or posterior vagina and lifting anteriorly [Figure 6]. As the anterior dissection proceeds distally the Small Grasper in Arm 1 is left in an open position and used to provide strong anterior counter retraction while Arm 2 places gentle traction on the rectum in a posterior vector. This allows the dissection to progress down to the pelvic floor. This is particularly useful in a deep narrow male pelvis. In patients with an anterior tumor, our dissection plane is always anterior to Denonvillier's Fascia. With posterior based tumors, our dissection plane is just posterior. The peri-prostatic nerve plexus carries mixed sympathetic and parasympathetic fibers and may be injured during this phase of the dissection.

A total mesorectal excision is completed circumferentially to the pelvic floor for patients undergoing coloanal anastomosis. For more proximal tumors, the dissection proceeds to a level that includes a 5cm distal mesorectal margin. In this case, the mesorectum at the distal transection point is ligated using the robotic vessel sealer in order to isolate the rectum and

prepare it for transection ensuring a tumor-specific mesorectal excision. The rectum is then divided with the robotic green load stapler completing the pelvic dissection [Figure 7].

In patients undergoing abdominoperineal resection (APR), the rectal dissection proceeds robotically to the pelvic floor in a cylindrical manner. The bare area of the rectum distal to the mesorectum must not be unroofed. In this scenario, the pelvic floor musculature can even be incised from the pelvis and the ischioanal space entered, exposing the ischioanal fat. The perineal portion of the resection is then conducted in the usual open fashion and the rectum is extracted through the perineum. Finally, the abdomen is insufflated after closure of the perineal incision and the end-colostomy is identified and matured usually in the left lower quadrant.

Figure 6. The anterior dissection, either anterior or posterior to Denonvillier's fascia (dependent upon tumor location), is performed by placing the rectum on tension in a posterior and cephalad direction (Arm 1). Arm 2 retracts anteriorly, and Arm 4 is performing the dissection (these may be interchanged). Additional counter traction can be obtained by having the assistant either retract posteriorly (as shown) or anteriorly.

Figure 7. The robotic stapler is utilized to transect the rectum (here for an LAR). The mesorectum has already been cleared with the robotic vessel sealer.

Step 4 – Medial-to-Lateral and Splenic Flexure Mobilization

At this point the robot is undocked and the boom is reversed with the splenic flexure selected as the new target anatomy. The patient is placed in reverse Trendelenburg and right side down. The camera is moved to Arm 2, the Small Graptor is placed in Arm 1, and the monopolar shears are placed in Arm 3. Arm 4 is undocked and utilized by the assistant to aid in retraction [Figure 8]. Arm 1 and the assistant elevate the descending colon mesentery and the previous medial dissection plane is identified. Utilizing a combination of monopolar and blunt dissection the embryologic planes are carefully separated. It is imperative to ensure that Toldt's fascia is preserved and the retroperitoneum is not violated – doing so places the retroperitoneal structures (kidney, ureter, and gonadal vessels) at risk of injury. This dissection is complete when all that remains of the colonic attachments are the lateral peritoneal attachments and filmy attachments to the splenic flexure. These attachments are divided with the monopolar shears completing the mobilization of the left colon. At this point 3 cc of Indocyanine Green (ICG) are injected intravenously and the Intuitive Surgical Firefly Fluorescence Imaging is utilized to evaluate the blood supply of the descending colon [Figure 9A/B] and rectal stump.

If an APR is to be performed, it is not necessary to mobilize the splenic flexure. The colonic mesentery is instead transected with the vessel sealer to the border of the sigmoid colon and the colon is divided with the robotic blue load stapler.

Figure 8. Trocar positions for splenic flexure mobilization.

Figure 9 A/B/C. Fluorescence angiographic imaging evaluates the blood supply of the bowel prior transection and to performing an anastomosis.

Step 5 – Anastomotic Technique

The robot is again undocked and restored to the initial setup with the patient back in Trendelenburg position. A 5 cm Pfannenstiel incision is made and a small Alexis (Applied Medical, Rancho Santa Margarita, CA) wound retractor is utilized. The rectum and left colon are removed from the abdomen. The bowel is divided sharply at the previously marked point

of transection and a 29 mm EEA anvil is secured utilizing a 2-0 Prolene suture. The left colon is returned to the abdomen and the Alexis wound retractor is sealed with a laparotomy pad. Once pneumoperitoneum is restored a standard stapled end-to-end anastomosis is performed under direct robotic visualization. ICG and Firefly are again utilized to ensure excellent perfusion to the anastomosis [Figure 9C]. A standard leak test is then performed.

For those patients with a low rectal tumor and undergoing a handsewn coloanal anastomosis, a mucosectomy is completed just proximal to the dentate line. Placement of a Lone Star retractor (CooperSurgical, Trumbull, CT) generally provides adequate visualization. The mucosectomy is carried proximally to just above the anorectal ring. The pelvis is then entered from the perineal side just anterior to the coccyx. A finger placed into the pelvis, transanally, is then utilized to identify the correct plane of dissection to free the rectum circumferentially with electrocautery. When performing this dissection anteriorly, one must take care not to injure the urethra in males or the vagina in females. Once completely mobilized, the rectum may be extracted transanally and divided at the previously identified proximal transection point on the descending colon. A single layer hand-sewn coloanal anastomosis is then fashioned with interrupted absorbable sutures placed circumferentially.

A diverting loop ileostomy is routinely used in patients with low (below the anterior peritoneal reflection) anastomoses, or those patients who received pre-operative radiation therapy. Consideration for ileostomy reversal occurs 3 months after the index operation, or once any potential adjuvant therapy is completed.

RESULTS

Once the safety and feasibility of LTME for the management of rectal was proven data was needed to ensure equivalent long term oncologic outcomes to traditional open TME (OTME). This evidence was provided by three major randomized control trials including the MRC CLASSIC, COREAN, and COLOR II. In each of these trials the 3 and 5 years data revealed no statistically significant differences between LTME and OTME in terms of overall survival, disease-free survival, and local and distant recurrence [7, 8, 12, 14]. With the already proven short-term benefits of LTME many authors believed MIS for rectal cancer was the superior technique. Due to the complex nature of rectal cancer there was a call for additional large multicenter randomized trials. The ACOSOG Z6051 and ALaCaRT were two large non-inferiority trials performed to compare LTME to OTME. The results of both trials showed excellent quality amongst both surgical arms, but LTME failed to meet the criterion for noninferiority for pathologic outcomes when compared to OTME. These findings could not support routine use of LTME for rectal cancer until long term outcomes could be confirmed [15, 16]. Robotic TME (RTME) offered the potential for non-inferiority based upon the known technical advantages of the robotic platform over standard laparoscopic techniques.

The first robotic colorectal surgery was performed by Ballantyne et al. in 2001 utilizing the da Vinci robotic system as a potential solution to the pitfalls of laparoscopic colectomy [26]. Then in 2006 Pigazzi et al. developed the concept of RTME for rectal cancer. Their study compared short-term outcomes between RTME and LTME and showed the safety and feasibility of RTME [27]. Despite the technique of RTME being around for greater than a

decade, the available data primarily consists of single-center experiences and a few small prospective studies.

Although the data is limited the results have consistently shown that RTME is safe, feasible, and offers excellent short term and long-term outcomes [17, 18, 28-33]. In addition, these limited series on RTME have suggested other potential areas of improved outcomes including decreased intra operative blood loss, higher lymph node harvest, shorter length of stay, and improved surgical margins when compared to LTME. Although these particular findings remain inconsistent RTME has consistently shown improved genitourinary function and lower conversions rates [17, 32, 34-39]. Additionally the robotic platform allows for the use of Firefly Fluorescence Imaging in conjunction with ICG. In a large prospective database study 436 consecutive patients underwent robotic assisted sphincter sparing surgery for rectal cancer. The authors showed a 10.6% change in operative decision which correlated to a decrease in anastomotic leak rate between the control and ICG group of 5.4% and 0.8% respectively ($p = 0.031$) [40].

There are however, important potential negatives of RTME which must be mentioned. The two most significant disadvantages include short term operational and inventory cost and increased operative times [17, 31, 33, 36, 37]. These negative findings have been a major barrier to more widespread adoption of robotic colon and rectal surgery. With increasing surgeon experience and the Xi robotic platform current data has shown decreased operative times and near equivalent costs when accounting for conversion rates and high volume robotic surgeons [41-43].

With limited quality data available on RTME there was a need for a large randomized trial. In response to this the ROLARR Trial was designed. This trial was a large international, multicenter, randomized, unblinded, parallel group trial that was designed to provide quality data on the safety and efficacy of RTME for the treatment of rectal cancer. 471 total patients were randomized to robotic-assisted or conventional laparoscopic surgery. The overall conversion rate to open laparotomy was 10.1% with 12.2% in the conventional laparoscopic group and 8.1% in the robotic assisted group ($p = 0.16$). Unfortunately, the study was dramatically underpowered due to poor study design and allowed surgeons with limited robotics experience (10 or more robotic procedures) to participate. Despite these limitations there was a significant difference noted in conversion rates for male patients (16.4% vs 8.7%, $p = 0.04$). In addition the robotic arm had a rate of CRM+ of 5.1% which is the lowest CRM+ rate when compared to COLOR II, MRC CLASSIC, ALACART, and ACOSOG Z6051. There were otherwise no significant differences identified in any of the secondary outcomes including intraoperative complications, postoperative complications, mortality, resection margin positivity, bladder dysfunction, and sexual function. Although this trial failed to demonstrate improved conversion rates with RTME it did confirm that RTME is safe and feasible in the largest robotic randomized trial to date [44].

CONCLUSION

Robotic rectal resection is both safe and feasible. Not unlike laparoscopic rectal resection the results of robotics appear to be in line with these historical works within MIS. As adoption of new MIS technique like RTME for rectal cancer expand it will be critical that

new research be engaged to demonstrate the value and challenges of this new technology. To date however, RTME has demonstrated itself to be a uniquely adaptable platform with outcomes equal to those of other forms of MIS. The future will help us demonstrate if the current outstanding short-term outcomes will translate into long-term improvements in morbidity and oncologic quality.

INTRODUCTION

A hernia is defined as an anatomical part which protrudes through an opening, tear, or weakness of the abdominal wall [1]. This defect may be congenital or acquired; due to muscle weakness or previous incision. Hernias are classified by type (primary or incisional), location, and size. While most abdominal wall hernias are congenital, a large proportion (42%) are acquired [2]. Incisional hernia occurs frequently (11-20%) following midline laparotomy [3]. Up to 5 million open abdominal operations are performed annually in the United States so the number of people likely to develop incisional hernia is quite high. An estimated 350,000 to 500,000 abdominal wall hernias then may be repaired annually in the United States.

Groin hernias are comprised of inguinal (96.3%), femoral (3%), and obturator hernias (0.7%). They have a bimodal distribution with a higher lifetime risk among men (27%) than women (3%). Up to 750,000 groin hernia repairs are performed annually in the United States and most are repaired using an open approach [4, 5]. Despite evidence demonstrating the benefits of a minimally invasive approach to groin hernias including low rate of surgical site infection, minimal postoperative pain, and early return to activity, the frequency of laparoscopic and/or robot-assisted groin hernia repair is relatively low (4-30% of all repairs). Recent research supports the use of minimally invasive groin hernia repair with equivalent rates of recurrence compared to open tension-free mesh repairs [6, 7]. The limited adoption of minimally invasive techniques may be due to lack of surgeon training, experience, and/or equipment as well as cost [8].

With the introduction of surgical robotic platforms, a growing number of groin hernias are now repaired using a minimally invasive approach. In 2016, the proportion of groin hernias repaired using a robot-assisted technique approached 20% of all repairs in the United

States. Most of these cases represent a shift from an open to minimally invasive approach, thereby increasing the total proportion of patients who benefited from a minimally invasive approach to groin hernia repair. The reason for this trend is multifactorial but certainly benefits offered by the surgical robotic platform play a role. Advantages of a robotic surgical platform include but are not limited to superior 3-dimensional visualization, stability of the platform, articulating instrumentation, and ergonomic benefits to the operating surgeon. Potential technical benefits related to visualization and stability of the surgical robotics platform include ease of enterolysis, dissection of the hernia sac and contents, approximation of fascia (and diastasis recti), and fixation of mesh [9]. There is also improved ergonomics for the operating surgeon, especially with angulation of instruments to perform dissection in various directions along the abdominal wall [7]. Theoretically, less trauma and pain may occur at trocar sites as the fulcrum for angulation is shifted from the abdominal wall (for laparoscopy) to the instrument (for robotics).

The robotic surgical platform facilitates various approaches to ventral and incisional hernias compared to the traditional laparoscopic intraperitoneal onlay mesh (IPOM) repair. These additional robotic-assisted techniques include transabdominal pre-peritoneal (TAPP) repair, Rives-Stoppa procedure, and posterior component separation (PCS) technique. With more options the surgeon can safely and effectively repair increasingly complex and larger defects previously repair using an open approach.

BACKGROUND

Hernia repair can be traced back to the early Egyptians as described by Georg Moritz Eber's ancient papyrus dated 3,000 to 2,500 B.C. [10]. Since then, hernia management has shifted from non-operative to operative strategies as people developed an understanding of the abdominal wall and groin anatomy. An initial operative technique was described by Lucas-Championniere, who included excision of the hernia sac and closure of the defect as key components of hernia repair [11]. William Mayo proposed the "pants over vest" technique [12]. Recurrence was a persistent problem until the introduction of knitted polypropylene mesh in the early 1950s [13]. Utilization of mesh allowed surgeons to decrease recurrence rates from 24-54% to 10-20%.

The first laparoscopic inguinal hernia repair (IHR) was performed by Ralph Ger in 1982 wherein he used metallic clips to close the hernia sac without mesh [14]. Ten years later a prosthetic mesh was utilized in conjunction with laparoscopic inguinal hernia repair [15]. Complications of IPOM include adhesions and bowel erosion, prompting surgeons to vary mesh placement based on anatomical locations. Access to the preperitoneal space was described either through the transabdominal preperitoneal (TAPP) approach or the totally extraperitoneal (TEP) approach, in which an endoscopic hernioplasty is performed by dissecting the myopectineal orifice without entering the peritoneal cavity [15, 16]. Subsequently, LeBlanc and Booth published the first laparoscopic ventral hernia repair (VHR) which involved intraperitoneal onlay mesh (IPOM) secured with staples [17].

The United States Food and Drug Administration approved the first robotic surgical platform in 2000. Ballantyne et al. published the first series of robotic-assisted VHR in 2003 [18]. The robotic surgical platform allowed for easier primary closure of the defect because of

wristed instruments [18-20]. A decade after, utilization of the robotic surgical platform for hernia repair has increased as various open techniques were adapted to a minimally invasive approach. This allowed for repair of more complex and larger hernia defects, decreased length of stay with decreased pain scores and decreased morbidity from large incisions.

OPERATIVE TECHNIQUE – VENTRAL/INCISIONAL HERNIA

The advantages of minimally invasive hernia repair are well described; however, certain barriers limit its widespread adoption. These potential barriers include the need for laparoscopic equipment, the technical difficulty, and the associated learning curve, especially in dissection and suturing of the anterior abdominal wall [7, 9]. The robotic surgical platform facilitates dissection of preperitoneal and retromuscular planes, closure of defects in typical and atypical locations, separation of components as needed, and placement of mesh in locations other than the peritoneal cavity. While not necessary in every situation, restoration of the lineal alba during VHR improves isokinetic and isometric measurements of the rectus abdominis muscle specifically and abdominal wall functionality and quality-of-life generally [21].

Patient Selection

The first phase in selecting patients for robotic-assisted ventral hernia repair (RVHR) is prehabilitation. The second phase is choosing an appropriate operative approach. Before selecting a robotic-assisted approach, the operating surgeon must consider the medical and surgical history, hernia characteristics, as well as individual training and experience. When these two phases are combined, the correct patient is matched to the correct operative approach.

In general, patients should be smoke-free for at least 4 weeks preoperatively to minimize the risk for surgical site infection (SSI). Patients with body mass index (BMI) of 35 to 39 kg/m² with co-morbidities and those with BMI of 40 kg/m² or greater who wish to undergo RVHR should be counseled about and in some cases required to participate in either medically supervised weight loss or surgical weight loss before VHR. Surgeons must not miss a critical opportunity to offer appropriate counseling and referral of patients with obesity to physicians and/or surgeons who specialize in weight loss. Besides smoking cessation and weight loss, patients are assessed for diabetes mellitus and history of wound infection. Patients with elevated hemoglobin A1c (>8%) are referred for better blood glucose control. Those with a history of SSI, especially with methicillin-resistant *Staphylococcus aureus* (MRSA), may benefit from MRSA eradication and/or antibiotic treatment. Consider the patients' nutritional status before undertaking RVHR. Patients are at risk of SSI and/or poor outcomes when nutritional status is poor.

Room Setup

Operating room setup is important to allow appropriate patient positioning and safety. The orientation of the operating table within the operating theater may vary depending on the model and mobility of robotic equipment as well as room size. Assuming a square-shaped operating room, the operating table is placed in the middle of the room. As routine, anesthesia personnel and equipment are located at the patient's head. The robotic platform can be positioned perpendicular to the operating table from the patient's left or right side (side-docking). If the hernia defect is off midline, the robotic platform should be docked from the ipsilateral side.

When setting up the operating room for RVHR, consider positioning the robotic equipment cart in a location where the cords do not compromise the safety of operating room personnel, ensuring the surgical assistant or technologist has unrestricted access to the patient, and the surgeon console is located away from the sterile field. Closed loop communication among operating room personnel is critical when the operating surgeon is physically separated from the patient (Figure 1).

Room Setup and Docking: VIHR

Figure 1. Operating room setup, patient positioning, and platform (da Vinci Si, X, and Xi, Intuitive Surgical, Inc.) docking are important for robotic-assisted ventral/incisional hernia repair.

Patient Positioning

Patients are positioned supine on the operating table with bilateral lower extremity sequential compression devices. The patient should be situated such that the mid abdomen overlies a flex joint in the operating table. In most cases, the patient's arms are tucked with care to protect intravenous access and provide padding of pressure points. One tip is to avoid bulky anterior and medial padding of the arms, as this may limit access to the lateral abdominal wall (or flank), a region commonly chosen for trocar placement. Very thin patients, especially those with medium-sized ventral hernias requiring a lateral trocar position, can be positioned off-center on the operating table with both arms tucked. This off-center positioning minimizes the risk for collision of the robotic arms against the operating table once docked. For patients with a short torso, it may be beneficial to flex the operating

table and elongate the torso slightly. In some patients, the leg ipsilateral to the operative site may impede a robotic arm. By pushing both legs together away from the operative site, a greater angle at the hips allows for more mobility of the inferior robotic arm (Figure 1).

Trocar Placement

Several factors influence the type, number, and location of trocars placed for RVHR. The type and size of trocars may vary by robotic surgical platform, diameter of camera lens, and availability of instruments. At least 3 robotic trocars are required for RVHR.

Figure 2. Robotic trocar location varies based on patient surgical history, body habitus, torso length, and hernia size and location. Most commonly, these trocars are placed in a staggered fashion along an anterior axillary line.

Most often these trocars are placed along the anterior axillary line in a staggered fashion, with the camera trocar most posterior. A general rule is to space these trocars 6-8 cm from one another. When using the da Vinci Si or X (Intuitive Surgical Inc., Sunnyvale, CA), the trocars should be spaced 8 cm apart in the vertical plane to prevent robotic arm collisions. Give the advanced patient clearance feature, trocars can be placed only 6 cm apart in the vertical plane when using the da Vinci Xi (Intuitive Surgical, Inc., Sunnyvale, CA). A disposable laparoscopic trocar (assist port) can be placed opposite the robotic trocars when necessary for passage of large or heavyweight mesh, removal of foreign body mesh, or other assistance. Trocar location may vary based on patient surgical history, body habitus, torso length, and hernia size and location (Figure 2). Long robotic trocars (8 mm x 160 mm) can be helpful during RVHR by increasing robotic arm clearance and facilitating deeper dissection. Peritoneal access can be obtained at the surgeon's discretion.

Docking

Docking position depends on the platform model, correct room setup, and hernia characteristics. Some platforms may need to be arranged in the operating room on the side opposite the desired location for trocar placement. Specifically, the da Vinci Si and X

platforms are docked on the side opposite the robotic trocars while the da Vinci Xi platform can be docked on either side of the patient regardless of robotic trocar location (Figure 1). This simple docking strategy is effective for midline ventral and incisional hernias, but defects located in more challenging locations (flank, subxyphoid, suprapubic) may require alternative docking strategies. For repair of defects larger than 5 cm, double docking may be required and the patient is turned 180 degrees after completion of one side of dissection. A mirror image of trocar placement on the opposite side is replicated.

In certain situations, parallel docking or alternate-site docking may facilitate repair of hernias in difficult anatomic positions. For subxyphoid location, RVHR can be performed with trocars placed in the hypogastrium. In that case, docking (Si and X models) over the patient's left or right shoulder may facilitate in-line visualization and dissection as well as minimize robotic arm collisions. For suprapubic location, RVHR can be performed through trocars placed in the subcostal region. If trocars are placed in the subcostal area, the robotic surgical platform (Si and X models) can be docked diagonally from the hip or low lithotomy position. Use of the patient clearance feature available on the newest robotic surgical platform (Xi model) allows for improved range regardless of docking strategy and hernia location.

Dissection

After correct patient positioning, trocar placement, and docking, RVHR is dependent on careful enterolysis and reduction of hernia content. The 12 mm, 30 degree (up) endoscope is placed through the middle trocar. Robotic instruments are inserted under direct visualization. Most commonly an atraumatic grasper and curved scissors are used (Figure 3). One tip to reduce issues with dissection and eventual mesh placement is “ranging the robot,” which entails inserting all instruments and moving both instruments as far cephalad and caudad on the ipsilateral side of the camera as possible. The point of “ranging the robot” is to assure that the surgeon will be able to use both instruments to secure a sufficiently large mesh to the anterior abdominal wall.

Figure 3. Enterolysis is accomplished with a combination of gentle blunt dissection with atraumatic graspers and careful electrosurgery using robotic shears. In more difficult situations, enterolysis can be facilitated by selecting the robotic vessel sealer (which also serves as an atraumatic grasper) and robotic shears.

Use of ‘cut’ current at low voltage is preferred compared to ‘coagulation’ current for dissection. During dissection, care is taken to avoid disrupting the posterior fascia. The hernia sac may either be excised or plicated, to decrease rate of seroma formation. The operating surgeon may choose to dissect and reduce the hernia sac, though this is not required. It is the opinion of the authors that any surgeon who attempts more advanced approaches such as robotic transabdominal preperitoneal (TAPP) VHR or posterior component separation must be proficient with RVHR plus IPOM.

Defect Closure

Once enterolysis, reduction of hernia contents, and control of the sac are complete, the next step is defect closure. It is the opinion of the authors that diastasis recti should be addressed with VHR to improve postoperative cosmesis and abdominal wall function, and lower risk of hernia recurrence.

Figure 4. Measuring the length and width of the hernia defect before closure is critical to selecting an appropriate mesh size regardless of the robotic-assisted ventral/incisional hernia repair technique.

Figure 5. Closure of the ventral/incisional hernia defect is important to reestablish a more functional abdominal wall as well as prevent hernia recurrence.

After measuring the defect to determine appropriate mesh size, plication of diastasis recti and defect closure follows (Figure 4). The authors choose slowly absorbable barbed suture (#0 V-Loc™ 180 Wound Closure Device, Medtronic Inc., Minneapolis, MN) on a GS-21 needle measuring 30 – 45 cm for defect closure. Tips to facilitate proper fascial approximation include decreasing the pneumoperitoneum to 8-10 mmHg, ensuring adequate visualization with each stitch, and adhering to the short stitch technique (Figure 5).

Mesh Placement and Fixation – IPOM

After fascia approximation, mesh implantation is next. The authors prefer a barrier-coated permanent synthetic mesh (medium- or heavyweight polypropylene) for most defects. Mesh size is determined by hernia defect length and width prior to defect closure. Mesh location is centered about the defect by marking the center of the mesh, as well as the long axis such that both are identifiable. This assures mesh is not secured to the abdominal wall in an off-center location.

The mesh is secured to the anterior abdominal wall using one of several fixation strategies including suture fixation with interrupted transfascial stitches, circumferential fascial stitches, and/or tacks. The authors choose circumferential fascial stitches without tacks. If the mesh is larger than 10 x 15 cm in size, the authors use additional fixation in the form of a midline running stitch that secures the long-axis of the mesh to the linea alba. This tightens the mesh against the anterior abdominal wall and may decrease the space available for accumulation of seroma (Figure 6). Pitfalls to consider include ensuring enough working space by proper lateral trocar placement to minimize the difficulty of suturing the mesh on the ipsilateral side of the camera.

Figure 6. Robotic-assisted ventral/incisional hernia repair with intraperitoneal mesh (IPOM) is useful for smaller defects and those in atypical locations.

Once mesh is implanted, it is important to inspect for gaps around the perimeter of the mesh. If there are gaps (≥ 2 cm) between stitches, additional stitches are warranted to minimize risk for herniation of visceral contents. The authors recommend closure of all fascial defects (>1 cm), including all 10-12 mm trocar sites; however, there may be reasons to close 8 mm trocar sites at the discretion of the operating surgeon.

Compared to conventional laparoscopic IPOM, various modifications have been considered to evaluate possible differences in outcomes related to post-operative pain [22]. Circumferential suturing of the mesh has been described by Allison et al. as an alternative to trans-fascial suture placement and tackers which may be a source of post-operative pain [23]. In 13 patients with up to a 23 month follow up, these authors reported no chronic suture pain or discomfort in their patient cohort [23].

In a study by Rosen and colleagues, patients from the American Hernia Society Quality Collaborative database who underwent either laparoscopic IPOM or robotic-assisted IPOM were propensity-matched and compared for hospital length of stay and surgical site occurrence at 30 days postoperatively [24]. After propensity matching, 454 patients in the laparoscopic IPOM cohort were compared to 177 patients who underwent robotic-assisted IPOM. The results confirmed a shorter median length of stay (0 vs 1 days; $P < 0.001$) and lower rate of surgical site occurrence (5 vs 14%; $P = 0.001$) among patients who had robotic-assisted IPOM repair. However, operative times of greater than 2 hours were more frequent for robotic-assisted IPOM repair, which may be related to surgeon's learning curve, docking and instrument exchanges [24].

Mesh Placement and Fixation – TAPP

The preperitoneal space is useful to avoid direct contact of mesh on viscera, reported to cause increased number and density of adhesions, bowel erosions, and mesh-related infections. The preperitoneal plane allows utilization of less expensive non barrier-coated synthetic mesh. It has also lead to the discovery of occult hernias not evident in preoperative assessment or imaging nor during diagnostic laparoscopy. Missed hernia defects may account for a proportion of recurrences which could have been addressed during the initial VHR.

Sarli et al. compared TAPP to IPOM and showed similar complication rates but lower recurrences after robotic-assisted TAPP repair [25]. The robotic-assisted TAPP repair should be considered when hernia defects can be closed primarily without the need for component separation. Feasibility of this technique was reported by Sugiyama et al. who described better ergonomics with wristed instrumentation compared to standard laparoscopic instruments when creating and closing peritoneal flaps [26]. The preperitoneal plane may provide a better environment for mesh isolation and integration.

After operating room setup, patient positioning, trocar placement, and docking as described above, the next step is dissection which varies compared to IPOM. Dissection begins with “ranging the robot” and ensuring sufficient distance of the camera from the hernia defect to allow adequate dissection and closure of the peritoneal flap. The dissection is initiated by incising the peritoneal flap at least 3 cm away from the camera tip (Figure 7). It is continued until at least a 5 cm overlap in all directions of the hernia defect is obtained. The sac is completely reduced and may be excised. Tears in the peritoneal flap must be closed preferably using rapidly absorbable braided suture in a figure-of-eight fashion to prevent

intraparietal hernia. The defect is closed and mesh is selected based on original defect size to provide adequate overlap. The mesh may be secured per surgeon preference using self-adhesive mesh, fibrin sealant, sutures, or in rare instances, tacks (Figure 8). The peritoneal flap is then closed using a running 2-0 barbed slowly absorbable suture in a running fashion. Should the peritoneum tear beyond repair or fail to dissect off the posterior rectus sheath, the surgeon should consider an IPOM as described previously.

Figure 7. Robotic-assisted ventral/incisional hernia repair with preperitoneal mesh (TAPP) is useful for smaller to medium-sized hernia defects. The procedure begins with “ranging the robot” then initial dissection of the peritoneal flap.

Figure 8. Robotic-assisted ventral/incisional hernia repair with preperitoneal mesh (TAPP) is useful for smaller to medium-sized hernia defects. The procedure includes defect closure and implantation of mesh in the preperitoneal space.

Mesh Placement and Fixation – Retrorectus

The original procedure which revolutionized hernia repair was initially described by Jean Rives and Rene Stoppa in France in the 1960s. They described restoration of the linea alba and reinforcement with prosthetic mesh, which was placed in a sublay position eliminating morbidity associated with mesh against viscera and the creation of subcutaneous flaps. Overall recurrence rates at long-term follow-up ranged from 3.9% to 10.9%. Wound morbidity is up to 13% with surgical site and mesh infection rate at 4%; seroma and hematoma formation at 4% [30-34].

Figure 9. Robotic-assisted ventral/incisional hernia repair with retromuscular mesh (Rives-Stoppa) begins with incising the posterior rectus sheath using robotic shears.

The operation begins with correct operating room setup, patient positioning, trocar placement, and docking as described above. As with other repair techniques, dissection begins with “ranging the robot,” enterolysis, and reduction of hernia contents. At a location approximately 2 cm medial to the linea semilunaris, the posterior sheath is incised vertically using robotic scissors with monopolar electrosurgery to expose rectus abdominis muscle fibers (Figure 9). Care should be taken during cephalad and caudad incision of the posterior rectus sheath to ensure the line of division remains medial to the linea semilunaris. The curvilinear incision of the posterior rectus sheath should extend at least 5 cm cephalad and caudad to the respective edges of the defect. Dissection proceeds from lateral to medial until the linea alba is reached (Figure 10). It is important to remain in the preperitoneal plane when crossing the linea alba as there is risk of incising the linea alba itself. During this crossover, the hernia sac is reduced from the subcutaneous tissue. Once across the linea alba, the contralateral posterior rectus sheath is incised vertically to enter the retromuscular space. Dissection proceeds from medial to lateral as far as the linea semilunaris. Care is taken to avoid injury to the neurovascular bundles. This will result in a large flap of posterior rectus sheath separated in the midline by peritoneum. Any peritoneal defects should be closed using

rapidly absorbable braided suture in a figure-of-eight fashion before the next step. Once the retrorectus space is dissected adequately, the hernia defect and resultant space are measured to choose the mesh of correct size and shape. The anterior fascial defect is then closed using a slowly absorbable barbed suture in a running fashion with short-stitch technique. Next, non-barrier-coated synthetic mesh is placed and secured within the retrorectus space. Finally, the posterior rectus sheath is approximated using absorbable barbed suture in a running fashion (Figure 11). It is critical to use a short-stitch technique to minimize the risk of acute intraparietal hernia postoperatively.

Posterior Component Separation

The transversus abdominis release (TAR) was described initially by Novitsky and colleagues [35]. In all, 428 patients underwent open TAR from 2006 to December 2014, with mean hernia defect area of 606 cm² and mesh area of 1220 cm². Of the 81% with at least one year follow-up, the rates of hernia recurrence, surgical site occurrence, and surgical site infection were 3.7%, 18.7%, and 9.1%, respectively [35]. These early data demonstrated the feasibility, safety, and short-term efficacy of TAR.

TAR as a technique has increased worldwide, with a growing number of TAR cases performed using minimally invasive techniques. Two recent studies demonstrated the potential benefits of robotic-assisted TAR for complex ventral and incisional hernia.

Bittner et al. conducted a single-center review of patients who underwent open or robotic-assisted TAR from 2015 to 2016 [36]. In total, 102 patients were analyzed (76 open TAR and 26 robotic-assisted TAR). Patients were comparable regarding age, gender, body mass index, and the presence of co-morbidities. Most hernia defects were midline (89.5 vs. 83%, $P = 0.47$) and recurrent (52.6 vs. 58.3%, $P = 0.65$). Hernia characteristics were similar regarding mean defect area (260 ± 209 vs. 235 ± 107 cm², $P = 0.55$), mesh removal, and type/size mesh implanted. Robotic-assisted TAR took longer to perform but trended toward lower morbidity (39.2 vs. 19.2%, $P = 0.09$), less severe complications, and similar rates of surgical site events and readmission (6.6 vs. 7.7%, $P = 1.00$) compared to open TAR. In addition, robotic-assisted TAR resulted in a significantly shorter median hospital length of stay compared to open TAR (6 days, 95% CI 5.9–8.3 vs. 3 days, 95% CI 3.2–4.3). The authors concluded that in select patients, the robotic surgical platform facilitates a safe, minimally invasive approach to complex abdominal wall reconstruction, specifically TAR. It also offers the short-term benefits of low morbidity and decreased hospital length of stay compared to open TAR [36].

Novitsky et al. compared 38 consecutive patients who underwent robotic-assisted TAR to 76 patients who had open TAR [37]. Patients who underwent robotic-assisted TAR experienced less intraoperative blood loss (49 ± 60 vs. 139 ± 149 mL, $P < 0.001$) and systemic complications (0 vs. 17.1%, $P = 0.026$) as well as shorter mean hospital length of stay (1.3 ± 1.3 vs. 6.0 ± 3.4 days, $P < 0.001$) compared to those who had open TAR. Surgical site events and infection were similar, but wound morbidity was lower after robotic-assisted TAR [37].

Figure 10. Robotic-assisted ventral/incisional hernia repair with retromuscular mesh (Rives-Stoppa) continues by crossing the linea alba to enter the contralateral retromuscular space.

Figure 11. Robotic-assisted ventral/incisional hernia repair with retromuscular mesh (Rives-Stoppa) concludes by approximation of the posterior rectus sheath using slowly absorbable barbed suture.

Regarding the technique for robotic-assisted TAR, the operation begins with correct operating room setup, patient positioning, trocar placement, and docking as described above. As with other repair techniques, dissection begins with “ranging the robot,” enterolysis, and reduction of hernia contents. It is important to note during operating room setup that this procedure requires docking the robot from both right and left sides of the patient (double docking). The next step is dissection of the posterior rectus sheath to the linea semilunaris followed by incision of the posterior lamina of the internal oblique fascia approximately 2 cm medial to the linea semilunaris and neurovascular bundles (Figure 12). This reveals transversus abdominis muscle, which is then transected in its entirety (Figure 13). The next

step is dissection of the transversus abdominis muscle off the transversalis fascia (posterior component separation), and separation of the peritoneum from overlying fascia extending from the diaphragm to space of Retzius and laterally to the retroperitoneum and psoas muscle (Figure 14). In addition, dissection of the myopectineal orifice assures identification and reduction of groin hernia or cord lipoma when present. Next, the posterior rectus sheath is approximated in a running fashion. A large-sheet mesh is placed in the retromuscular/preperitoneal position and secured using either transfascial sutures and/or fibrin sealant (Figure 15). Finally, the anterior rectus sheath is approximated using a 4:1 suture-to-wound-length ratio and short-stitch technique with slowly absorbable barbed suture [36].

Figure 12. Robotic-assisted ventral/incisional hernia repair with transversus abdominis release (TAR) constitutes an advanced robotic operation. Key anatomic structures include the linea semilunaris and the neurovascular bundles.

Figure 13. Robotic-assisted ventral/incisional hernia repair with transversus abdominis release (TAR) proceeds with identification and complete transection of the transversus abdominis muscle to reveal the transversalis fascia.

Figure 14. Robotic-assisted ventral/incisional hernia repair with transversus abdominis release (TAR) continues with lateral dissection of the peritoneum off the internal oblique muscle and transversalis fascia.

Figure 15. Robotic-assisted ventral/incisional hernia repair with transversus abdominis release (TAR) concludes with implantation of large, flat sheet mesh secured with either sutures or fibrin sealant.

Diastasis Recti

We recommend repair of diastasis recti associated with midline ventral hernia defects to allow for proper restoration of the linea alba and improve the biomechanics of the abdominal wall. This can be done using a permanent barbed suture in a running fashion to plicate edges of the rectus abdominis muscle to restore the linea alba in conjunction with the hernia repair.

Recurrent Ventral/Incisional Hernia

Selecting the appropriate patient for robotic assisted hernia repair is of paramount importance. This include pre-operative planning to optimize glucose control, weight and ensuring adequate nutritional status. Obtaining a pre-operative CT scan to evaluate the actual size of the hernia defect and its precise location must be considered in order to plan for appropriate technique utilized. Patient's with loss of domain, those with fistulas or ongoing mesh infection should be avoided.

Figure 16. Recurrent ventral/incisional hernia repair may require removal of foreign body including sutures, tacks, and mesh.

The positioning, and docking are similar for midline incisional hernias. Technical aspects will include lysis of adhesions to the posterior abdominal wall and explant of existing mesh which at times may be difficult with adherence to either bowel, or within the posterior sheath (Figure 16). This may be performed sharply using scissors or with electrocautery. This will then dictate the plane available for mesh placement and the need for posterior separation of components to achieve primary closure.

OPERATIVE TECHNIQUE – GROIN HERNIA

The advantages of minimally invasive compared to open inguinal hernia repair (IHR) include lower rates of surgical site infection and acute postoperative groin pain and earlier return to work [6, 7]. Robotic-assisted repair of groin hernia employs a TAPP technique. Published data demonstrates its feasibility and safety with similar recurrence rates and post-operative pain. Studies describe advantages including ease of dissection and suturing due to improved dexterity [39].

Bittner and colleagues compared patients' perceptions of acute postoperative groin pain, activity limitation, and overall satisfaction after robotic-assisted-, laparoscopic, or open

IHR [40]. Random samples of patients from two web-based research panels and surgical practices were screened for patients who underwent IHR between 2015 and 2016. Qualified patients were surveyed to assess perceived acute postoperative groin pain at 1 week postoperatively, activity disruption, and overall satisfaction. Three cohorts based on operative approach were compared. Propensity scoring resulted in 83 robotic-assisted IHR matched to 83 laparoscopic IHR respondents, while 85 robotic-assisted IHR matched with 85 open IHR respondents. The robotic-assisted IHR respondents recalled less acute postoperative groin pain compared to respondents who had open IHR (4.1 ± 0.3 vs 5.6 ± 0.3 , $P < 0.01$) but similar pain compared to laparoscopic IHR (4.0 ± 0.3 vs 4.4 ± 0.3 , $P = 0.37$). Respondents recalled less activity disruption 1 week postoperatively after robotic-assisted IHR versus open IHR (6.1 ± 0.3 vs 7.3 ± 0.2 , $P < 0.01$) but similar levels of activity disruption after laparoscopic IHR (6.0 ± 0.3 vs 6.6 ± 0.27 , $P = 0.32$). At the time of the survey, respondents perceived less physical activity disruption after robotic-assisted compared to open IHR (1.4 ± 0.2 vs 2.8 ± 0.4 , $P < 0.01$) but similar to laparoscopic IHR (1.3 ± 0.2 vs 1.2 ± 0.2 , $P = 0.94$). The authors concluded that patient perceptions of pain and activity disruption differ by approach, suggesting a potential advantage of a minimally invasive technique over open for IHR [40].

PATIENT POSITIONING, TROCAR PLACEMENT, AND DOCKING

Patients are positioned supine on the operating table with bilateral lower extremity sequential compression devices. In most cases, the patient's arms are tucked with care to protect intravenous access and provide padding of pressure points. For patients with a short torso, it may be beneficial to flex the operating table and elongate the torso slightly. Ultimately, the operating table is moved to a Trendelenberg position to permit better visualization of the myopectineal orifice.

Figure 17. Robotic-assisted inguinal hernia repair begins with proper trocar placement in a staggered fashion, with the camera trocar positioned at or cephalad to the umbilicus and 1-2 cm lateral to midline. A general rule is to space these trocars 6-8 cm from one another.

Several factors influence the type, number, and location of trocars placed for robotic-assisted repair of groin hernia. The type and size of trocars may vary by robotic surgical platform, diameter of camera lens, and availability of instruments. At least 3 robotic trocars (8 mm) are required. Most often these trocars are placed in the epigastrium in a staggered fashion, with the camera trocar positioned at or cephalad to the umbilicus and 1-2 cm lateral to midline. A general rule is to space these trocars 6-8 cm from one another. A disposable laparoscopic trocar (assist port) can be placed when necessary for passage of large or heavyweight mesh, removal of foreign body mesh, or other assistance. Peritoneal access can be obtained at the surgeon's discretion (Figures 17).

**Si Positioning / Docking
Left Inguinal Hernia**

**Xi Positioning / Docking
Inguinal Hernia**

Figures 18-19. Robotic-assisted inguinal hernia repair proceeds with docking, which can vary depending on the robotic surgical platform. The da Vinci Si and X platforms are most often docked at an angle while the da Vinci Xi platform may be side-docked in all situations (Intuitive Surgical Inc., Sunnyvale, CA).

Docking position depends on the platform model and correct room setup. Most often side-docking or angled docking suffice, but in certain situations parallel docking or alternate-site docking may facilitate repair of hernias. If trocars are placed in the subcostal area (epigastrium), the robotic surgical platform can be docked diagonally from the hip or low lithotomy position. Use of the patient clearance feature available on newer robotic surgical platforms allows for improved robotic arm range (Figures 18 and 19).

Dissection

After identifying landmarks including the median umbilical ligaments, anterior superior iliac spine, and inguinal canal, a peritoneal flap is created using robotic shears and monopolar electrocautery. It is important to identify the transversalis fascia and keep dissection posterior to protect the lateral femoral cutaneous nerve and genitofemoral nerve. Goals during lateral dissection of the myopectineal orifice is to avoid exposure of nerves, expose the psoas muscle, and minimize the use of monopolar electrocautery to prevent postoperative groin pain. Dissection medial to the inguinal canal proceeds by developing the space of Retzius to expose the pubic tubercle and Cooper's ligament, the direct inguinal space, and to define the obturator canal, femoral canal, and medial border of the external iliac vein. The inferior epigastric is identified and serves to delineate a direct inguinal hernia located medially from an indirect hernia. Any content or fat located in Hesselbach's triangle should be reduced.

Figure 20. Robotic-assisted inguinal hernia repair must achieve the critical view of the myopectineal orifice, which includes obturator canal, femoral canal, and direct and indirect inguinal region, and result in complete reduction of hernia content and sac(s).

Complete dissection medial and lateral to the inguinal canal results in the critical view of the myopectineal orifice, which is bounded superiorly by the internal oblique and transversus abdominis muscles, medially by the rectus abdominis muscle, laterally by the iliopsoas muscle, and inferiorly by the pubis (Figure 20). Finally, dissection of the inguinal canal includes complete reduction of any indirect hernia sac, isolation of the vas deferens and spermatic vessels or round ligament, and dissection and posterior reduction of the peritoneum off the spermatic cord or round ligament. Care should be taken to avoid grasping the vas deferens or the spermatic vessels directly; rather, grasping the surrounding tissue is preferred. The round ligament can be divided at the surgeon's discretion, preferably close to the

peritoneum rather than close to the internal inguinal ring to avoid injury to the genital branch of the genitofemoral nerve. The critical view of the myopectineal orifice is established in this manner [41].

Dissection must be completed in between the spermatic cord elements to avoid missing attachments of the sac. The femoral canal located medial to the femoral vein, lateral to the lacunar ligament and bounded superiorly by Cooper's ligament is evaluated for the presence of a femoral hernia. The peritoneum must be dissected lateral to the cord structures past the anterior superior iliac spine to allow at least a 10 x 15 cm mesh [41]

Mesh Placement and Fixation

The mesh is laid flat covering the myopectineal orifice with appropriate overlap to prevent a recurrence. Various flat sheet and anatomical mesh options are available (Figure 21). If fixation is deemed necessary, mesh may be secured with suture, fibrin sealant, or a self-fixating mesh may be utilized. The peritoneal flap is closed using either a 3-0 short-term absorbable barbed suture in a running fashion (Figure 22). It is important to close the flap or any other defect completely to prevent occurrence of an inter-parietal hernia.

Figure 21. Robotic-assisted inguinal hernia repair requires implantation of preformed polypropylene mesh to cover the entire myopectineal orifice. Fixation strategies may include no fixation, sutures, tacks, fibrin sealant, and/or self-fixating mesh.

Figure 22. Robotic-assisted inguinal hernia repair concludes with closure of the peritoneal flap using absorbable suture.

CONCLUSION

A robotic surgical platform facilitates a safe, minimally invasive approach to ventral/incisional hernia repair, with known benefits for complex abdominal wall reconstruction. Evidence shows that in the hands of experienced hernia surgeons, robotic-assisted ventral/incisional hernia repair with transversus abdominis release offers the short-term benefits of low morbidity, decreased hospital length of stay, and lower total costs compared to an open approach in select patients [36, 37]. These outcomes translate to value in the delivery of care for patients with ventral/incisional hernia. Similarly, a robotic surgical platform can yield improved short-term outcomes regarding acute postoperative groin pain and activity disruption in select patients with groin hernia [40]. As options for minimally invasive repair of ventral/incisional and inguinal hernia continue to grow, it is ultimately patients that will benefit.

INTRODUCTION

Hepatobiliary (HPB) surgery encompasses a complex group of procedures that are performed for a variety of benign and malignant indications.

The morbidity and mortality associated with HPB surgery has decreased over the last several decades due to advances in anesthesia, critical care and other aspects of peri-operative care. Improvement in surgical technique and instrumentation as well as regionalization of care to high volume centers has also led to improvement in outcomes.

The robotic platform provides significant advantages over standard laparoscopy enabling complex HPB procedures to be performed in a minimally invasive fashion. One of these is procedures is the pancreaticoduodenectomy (PD) which is a complex procedure involving the resection of the pancreatic head, uncinate process and duodenum followed by a complex reconstruction with three anastomoses in order to achieve physiologic continuity of the gastrointestinal tract.

The robotic platform provides improved optics with three-dimensional vision through a binocular scope, resulting in improved depth perception, higher magnification, and a stable camera image. Adjuncts such as built in fluorescence imaging and TilePro (Intuitive Surgical, Sunnyvale, CA) picture overlay while performing intra operative ultrasound (US) add to operative efficiency and improve outcomes. As a result of a surgeon controlled stapling device and a fully articulating, bipolar vessel sealing device, a single operating surgeon is able to perform procedures without the need for an assistant surgeon at bedside.

The ability to use fine suture to approximate small structures as part of a complex reconstruction is made possible by the ability to perform supra physiological movements with

the robotic needle drivers. This level of articulation is not possible with standard laparoscopic instruments. The robotic console also provides an ergonomic advantage, allowing a single surgeon to control three operative robotic arms while seated at the console eliminating the “stress” of the arm and hand movements as well as any tremor. The robotic platform therefore provides the tools required to perform complex HPB operations such as a PD in a minimally invasive fashion.

In this chapter, we describe the technical aspects of performing a robotic PD, distal pancreatectomy with splenectomy, and right hepatectomy. We also discuss the outcomes of robotic PD, in order to determine its safety and feasibility.

PATIENT SELECTION

Proper patient selection for robotic assisted HPB surgery cannot be overemphasized. This applies most during the early learning curve. More specifically, deciding whether to offer a patient a robotic assisted procedure depends on the indication for the procedure, individual patient factors, and where the surgeon is in his/her learning curve. Patient selection for both robotic hepatic resections and pancreatic resections are based on similar principles.

Indications for the Procedure and Technical Factors

Tumor pathology and its location is an important factor in determining whether a robotic approach is feasible. When evaluating patients for pancreatic disease, pre-operative pancreatic protocol CT scan and endoscopic ultrasound (EUS) are both commonly used to assess the size, location, and resectability of the tumor. The proximity to and possible involvement of vascular structures must be noted and considered prior to deciding whether to proceed with a robotic approach. In addition, a CT of the chest and abdomen must be performed to evaluate the lungs and liver for distant metastatic disease.

Large pancreatic tumors, those that are borderline resectable, or require concomitant vascular or multi visceral resection are not well suited for the robotic approach and should be avoided. A National Surgical Quality Improvement Program (NSQIP) study examining 30 day outcomes in laparoscopic and robotic PD patients found a higher overall complication rate and a higher conversion rate to an open procedure when it was associated with vascular reconstruction or multi visceral resection [1].

Similarly when planning a robotic hepatic resection, technical factors such as tumor size, and proximity to critical vascular structures determine feasibility of the robotic approach. These patients are evaluated with a triple phase CT scan of the liver. Tumors greater than six cm and those involving the inferior vena cava and/or portal vein bifurcation require maximal exposure best achieved with an open approach.

Learning Curve

During the initial learning curve associated with robotic HPB procedures, we recommended selecting relatively straightforward cases. These include but are not limited to cholecystectomy, distal pancreatectomy with splenectomy (DPS), and straightforward liver procedures. As experience and familiarity with the robotic platform increases, he or she may perform more complex cases such as PD.

During the initial experience with robotic PD, we recommend selecting patients with chronic pancreatitis, neuroendocrine tumors, cystic neoplasms, ampullary cancers and distal cholangiocarcinomas.

Increasing comfort with robotic HPB is reflected by a decrease in operative times and conversion rates to open thus allowing selection of more complex cases. During our initial experience, the ratio of conversion to open for robotic HPB cases was one in every four cases. This decreased significantly to one in every 32 cases later in our series. Simultaneously, operative times also decreased with the number of cases performed [2]. Over a two year period, the operative time in our series for a robotic PD decreased by 30 minutes [2].

This is similar to the data Boone et al. published regarding their learning curve for robotic PD [3]. They demonstrated that estimated blood loss (EBL) and conversion to an open procedure decreased significantly after the first 20 cases. Clinically relevant Grade B/C pancreatic fistulas (POPF) decreased by half after 40 cases with a significant decrease in operative times after 80 cases.

Patient Factors

Body habitus and co morbidities of the individual patient must be taken into consideration prior to proceeding with a robotic approach. Patients with pre operative dyspnea are associated with higher conversion rates to an open procedure [1]. Therefore, patients with high body mass index (BMI), and significant pre-operative cardiopulmonary disease should not be selected for the robotic approach. It is also prudent to avoid elderly frail patients, those with multiple prior abdominal surgeries (ventral hernia repairs with mesh) and patients with very low BMI's or petite body habitus.

OPERATIVE TECHNIQUE

Equipment

The da Vinci Surgical System Si or the Xi (Intuitive Surgical, Sunnyvale, CA) with the associated instrumentation is used. The Prograsp forceps, a fenestrated bipolar and monopolar scissors are used to perform most robotic assisted HPB cases. In addition, a robotic vessel sealer is key in facilitating dissection while achieving adequate hemostasis.

Table 1. Equipment for robotic HPB procedures

Items	Details (n: number required, if greater than 2)
Robotic system	Da Vinci™ Xi or Si system
Robotic instruments	30-degree camera Prograsp™ Fenestrated Bipolar Mono-polar scissors (2) Large and diamond needle drivers Bipolar vessel sealing device Large clip applicator Robotic bulldog clamps Ultrasound probe
Ports	(2) 12 mm assistant trocars (3-4) 8 mm robotic trocars
Basic laparoscopic tray	Veress needle Suction – irrigation Needle drivers Stapling devices on standby
Suture	0 Vicryl suture 4-0 V-lock 4-0 Monocryl, cut to 12 cm 5-0 Monocryl, cut to 12 cm 6-0 Monocryl, cut to 12 cm
Specimen bags	Cook LapSac™ – 5 x 8, 8 x 10 (inches)
Drains	19 French Blake drain
Retractor	Nathanson retractor

Figure 1. Needles used for robotic HPB procedures.

Locking plastic clips (Hemalok, Weck) are used prior to division of larger vessels while micro clips are used for smaller vessels. The operating surgeon using a robotic clip applicator fires the clips.

Large and diamond needle drivers are required and used for placement of sutures during the complex reconstructions. A wide range of sutures and needle sizes may be used with the robotic platform. Commonly used suture for our robotic procedures are barbed monofilament suture and monocryl (Ethicon, Inc., Somerville, NJ). Equipment and sutures are listed in Table 1 with needle sizes shown in Figure 1.

ROOM SET-UP AND PATIENT POSITIONING

Most operating rooms have designated robot OR suites where robot assisted procedures are performed. In order to optimize efficiency the OR suite must be set up based on the individual surgeons preferences, ahead of time. This requires determining appropriate placement of the robotic cart, console(s), and AV towers in relation to the scrub table and anesthesia. Movement of equipment on the morning of surgery should be avoided.

The set up varies depending on whether Si or Xi system is used. When using the Si system, following intubation, the patient table is placed at 90 degrees to anesthesia team. The patient is placed in supine position with slight flexion. The left arm is out while the right arm is tucked and they are placed in slight reverse Trendelenberg position as shown in Figure 2. The AV tower is placed at the foot of the bed and the robot cart docks directly above the head of the patient.

For the Xi system, following intubation, the patient table is placed at 45 degrees to the anesthesia team. Both arms are out and wrapped with the patient in supine position, slight flexion and slight reverse Trendelenberg. The robot cart docks to the right of the patient table.

Figure 2. Patient positioning for the Si system. The anesthesia team is to the left of the patient. The robot docks at the head of the patient.

Most robotic HPB procedures are performed with the patient positioning described above. Exceptions to this are right posterior sectionectomy without hilar dissection and non-anatomic segment 6 and 7 resections. These procedures require the patient to be placed in a left lateral decubitus right side up position.

ENTRY AND PORT PLACEMENT

A preferred reliable technique for access to the abdomen should be established. Access is obtained by making a one cm infra umbilical incision and the abdomen is insufflated using a Veress needle following which a 12mm bladeless trocar is used to obtain entry. Alternately, the Hassan technique may be used to gain access. In patients with a prior midline incision, insufflation may be obtained by placing a Veress needle in the left subcostal region in the mid clavicular line followed by entry with a 12mm bladeless trocar.

The robotic camera is used for initial diagnostic laparoscopy as well as for lysis of adhesions. This helps increase to efficiency and minimize cost by avoiding the need to open laparoscopy equipment.

Robotic HPB procedures require the use of three robotic working arms, a robotic camera port and an assistant port. The scrub technician uses the assistant port to suction and exchange sutures.

When using the Si system, the camera port is placed in the infra umbilical position approximately 16-20 cm from target anatomy and adjusted based on body habitus. In patients with a long torso, obesity or a low umbilicus, the camera port may be moved cephalad to a supra umbilical position. The robotic working ports are placed along a semi-circular line directed towards the target anatomy. The distance between each port is approximately eight to ten cm while maintaining at least a three cm distance from surrounding bony structures. If space is limited due to the patient's body habitus, the distance of the working ports from the camera port may be decreased.

The two main working ports are placed along the semi circular line, one on the left and the other on the right side. The robotic "third arm" is placed on the patient's left side as shown in Figure 3. The 12 mm assistant port is placed below the semi-circular line, outside of the ergonomic triangle in order to minimize collisions with the robotic ports. It should be at least 150 mm in length, and should be a balloon trocar if shorter.

Figure 3. Port placement with the Si system. Ports are placed along a semi-circular line 16-20 cm from target anatomy.

Figure 4. The infra umbilical 12 mm assistant port may serve as a robotic port for portions of the procedure.

When using the Xi system, the 12mm umbilical port is used as the assistant port during most of the procedure. This may also serve as a camera or robotic working port if needed, as shown in Figure 4. The robotic ports are placed along a straight line at variable distance from target anatomy depending on the patient's body habitus (Figure 5). The robotic camera is placed in the right mid clavicular line. Two working ports are placed on the left, with one on the right at distance of six to eight cm between each port.

Figure 5. Port placement for the Xi system. The ports are placed along a straight line. The camera port is placed on the patient's right in the mid-clavicular line.

With respect to closure of port site, it is out preference to close only 12 mm trocar sites with 0 vicryl (Ethicon, Inc., Somerville, NJ) using a suture passer. We do not routine close the 5 mm and 8 mm trocar sites. One of the 8 mm trocar sites is used for drain placement.

SINGLE SURGEON ROBOT ASSISTED PANCREATICODUODENECTOMY

Resection

We begin the procedure by inspecting the abdomen to rule out evidence of metastatic disease. It is our practice to use the falciform ligament as a vascularized pedicled flap. We therefore take down the ligament and preserve it (leaving it attached to the liver) to be used at the end of the case.

Retraction is then set up to expose the hilum. This is based on whether the patient has had a prior cholecystectomy. If the gallbladder is present, a stitch is placed securing it to the anterior abdominal wall (Figure 6). However, in the absence of the gallbladder, a Nathanson retractor is used (Figure 7).

Figure 6. Placement of a gallbladder stitch suspending it to the abdominal wall.

Figure 7. Using a Nathanson retractor for exposure of the hilum. This patient had a prior cholecystectomy.

The gastrocolic ligament is opened in an avascular plane using the monopolar scissors and taken down with the robotic vessel sealer as shown in Figure 8. The posterior stomach is then mobilized off the pancreas.

We then dissect and mobilize the distal gastric antrum and proximal duodenum using the robotic vessel sealer. During this dissection, the right gastro epiploic and right gastric vessels are identified, dissected and divided following the application of Hemalock clips (Figure 9). The hepatic flexure of the colon is then taken down using the robotic vessel sealer.

Our preference is to perform a pylorus preserving procedure. We therefore divide the proximal duodenum just distal to the pylorus using a 60 mm robotic stapler (Figure 10). The duodenum is then Kocherized using the robotic vessel sealer as shown in Figure 11.

Figure 8. Using the robotic vessel sealer to take down the gastrocolic ligament.

Figure 9. Division of the right gastro epiploic vein after placement of locking clips.

Using the monopolar scissors the hepatic artery is dissected and a portal and celiac lymphadenectomy is performed (Figures 12 and 13). The gastroduodenal artery is then identified, ligated and then clipped with Hemalock clips following which it is divided (Figure 14).

Figure 10. The robotic stapler is used to divide the duodenum just distal to the pylorus.

Figure 11. Kocherization of the duodenum.

Figure 12. Dissection of the porta hepatis.

Figure 13. Dissection of celiac lymph nodes and hepatic artery.

Figure 14. Ligation and clipping of the gastroduodenal artery.

Figure 15. Division of the jejunum 20 cm from the Ligament of Treitz.

The jejunum is divided approximately 20 cm distal to the ligament of Treitz using the robotic stapler as shown in Figure 15. The robotic vessel sealer is then used to seal the mesentery up towards the base of the uncinate process (Figure 16).

Figure 16. Division of the mesentery with the robotic vessel sealer.

The peritoneum overlying the inferior border of the pancreas is incised and the uncinate process is dissected using the monopolar scissors. Once they have been dissected and mobilized, a tunnel is created above the superior mesenteric vein and portal vein under the neck of and up to the superior border of the pancreas. An umbilical tape is then passed through this tunnel and approximated with a clip in order to facilitate pancreatic neck transection (Figure 17). The neck of the pancreas is transected using the monopolar scissors coupled with saline irrigation.

Following division of the pancreas, the uncinate process is dissected off the superior mesenteric vessels using a combination of the robotic vessel sealer and monopolar scissors (Figure 18). Venous branches draining the head of the pancreas and uncinate process are clipped with locking clips and divided during this dissection.

Figure 17. An umbilical tape is placed around the neck of the pancreas and a clip applied. This facilitates transection of the pancreas.

Figure 18. The uncinus process is dissected off the superior mesenteric vessels.

The cystic artery and duct are dissected, clipped with locking clips and divided. The common hepatic duct is then divided using the mono polar scissors just above the take off of the cystic duct (Figure 19). If a stent has been placed previously, it is removed and the specimen is placed in a retrieval bag for removal.

Figure 19. Division of the bile duct containing a stent.

Figure 20. Using intra operative US to visualize tumor location and the superior mesenteric vessels.

Intra operative robotic ultrasound is used throughout the procedure in order to identify and evaluate the vasculature prior to dissection and division of vessels (Figure 20).

Specimen extraction is done through the umbilical port. The port is enlarged to facilitate removal of the specimen bag. Following removal, the space is partially closed, allowing placement of a 12 mm trocar. The robotic camera is then switched to this port for the reconstruction phase of the procedure.

Reconstruction

A window is created in an avascular area of the transverse colon mesentery through which the previously stapled end of the jejunum is brought up to the vicinity of the pancreas for the reconstruction. The pancreaticojejunostomy is performed as a two layer, end to side anastomosis. A 5-0 monofilament suture is used to create the posterior layer of the anastomosis (Figure 21). The capsule of the pancreas and the seromuscular layer of the jejunum are approximated in running fashion.

Figure 21. Posterior capsule of the pancreaticojejunostomy. 5-0 mono filament suture is used in running fashion.

Using the mono polar scissors, a small enterotomy is made in the jejunum matching the diameter of the pancreatic duct. Using 6-0 monofilament sutures, a duct to mucosa anastomosis is performed in interrupted fashion (Figure 22). Stents are used variably depending on the diameter of the pancreatic duct. When used, the anastomosis is performed over a 5 or 8 French pediatric feeding tube or stent. The previously fashioned round ligament flap is then wrapped around the anastomosis.

The hepaticojejunostomy is performed approximately 10-15 cm downstream from the pancreatic anastomosis. Whether the anastomosis is performed in running or interrupted fashion depends on the size of the bile duct. When bile duct is small, the anastomosis is performed using a 4-0 or 5-0 monofilament suture in interrupted fashion. This is done to prevent possible stenosis of smaller bile ducts. Larger diameter bile ducts allow the anastomosis to be performed in running fashion with a 4-0 barbed suture, although care must be taken to avoid purse stringing and possible stenosis (Figure 23).

Figure 22. Duct to mucosa pancreaticojejunostomy using 6-0 monofilament suture in interrupted fashion.

Figure 23. Hepaticojejunostomy performed with 4-0 barbed suture in running fashion.

Figure 24. Ante colic duodenojejunostomy performed in running single layer fashion.

Our preference is to perform an ante colic duodenojejunostomy. A loop of the jejunal limb is brought up in ante colic fashion approximately 50 cm from the biliary anastomosis to the vicinity of the duodenal staple line. Once this is done without any tension, an enterotomy is made on the anti mesenteric border corresponding to the length of the duodenal staple line. The duodenal staple line is resected and the anastomosis is performed in single layer fashion. A barbed absorbable monofilament suture is used to take seromuscular bites in running fashion (Figure 24).

We place a single 19 French Blake drain in the vicinity of the pancreatic and biliary anastomosis. TISSEEL (Baxter Healthcare Corp., Deerfield, IL) is sprayed on all three anastomosis upon completion of the procedure.

DISTAL PANCREATECTOMY AND SPLENECTOMY

Exposure of the Pancreas

A ProGrasp forcep and fenestrated bipolar forcep are used to identify a relatively avascular plane in the gastrocolic ligament below the greater curve of the stomach. The robotic vessel sealer is then used to make a window in the ligament and gain entry into the lesser sac. The dissection is carried laterally to divide the splenocolic ligament. Medially, it is carried out up to the gastroepiploic vascular pedicle.

The posterior stomach is mobilized from the anterior pancreas by using the vessel sealer to take down any avascular congenital adhesions or adhesions from endoscopic ultrasound (EUS) biopsy. To facilitate exposure, the stomach is subsequently suspended to the anterior abdominal wall with a running barbed suture (Figure 25).

Figure 25. Suturing the stomach to the anterior abdominal wall to facilitate exposure.

Intra Operative Ultrasound

The location of the tumor and its relationship to key vascular structures are confirmed using an intra-operative ultrasound (Figure 26). In particular, the line of pancreatic transection

in relation to the portosplenic confluence and the location of the common hepatic artery are noted. The TilePro picture overlay function on the robotic platform enables simultaneous visualization of the ultrasound images and the operative field.

Figure 26. Intra operative US to localize the tumor and relationship to vasculature.

Dissection of the Pancreas and the Splenic Vessels

The peritoneum overlying the inferior border of the pancreas is incised with a monopolar scissor. Dissection is then carried out in the plane between the posterior pancreas and the retroperitoneum from medial to lateral. A combination of the fenestrated bipolar and monopolar scissors are used for dissection with the third robotic arm providing gentle anterior retraction of the pancreas. At the portosplenic confluence the dissection continues in this plane toward the superior border of the pancreas (Figure 27). Micro-clips are used to clip small venous branches draining the pancreas into the splenic vein.

Figure 27. The pancreas is gently retracted superiorly. Dissection in the avascular plane between the pancreas and retroperitoneum.

The peritoneum at the superior border of the pancreas is incised in similar fashion (Figure 28). The splenic artery is then identified and skeletonized close to its take off from the celiac axis by dissecting the surrounding lymphatic tissue (Figure 29). Intra operative ultrasound is again used to confirm isolation of the splenic artery to prevent inadvertent division of the common hepatic artery or celiac trunk. The artery can then be divided with a vascular load using the robotic stapler or endovascular stapler, depending on surgeon preference and availability of a bedside assistant (Figure 30). Alternately, locking plastic clips may be used, which is the author's preference in an effort to minimize the cost of the stapler.

Figure 28. Incision of the peritoneum overlying the superior border of the pancreas.

The tunnel from inferior to superior border of the pancreas is completed, following which the neck of the pancreas is encircled with a Dacron tape. The pancreas is then divided using a stapling device, which again, may either be a robotic or endovascular stapler.

Figure 29. Dissection of the lymphatic tissue around the celiac axis at the superior border of the pancreas.

Figure 30. Stapling the splenic artery.

Figure 31. Upon completion of the tunnel a Dacron tape is placed around the pancreas.

Figure 32. Stapling across the pancreatic neck.

The splenic vein is isolated (Figure 33) and divided distal to the portosplenic confluence and this again may be performed using a vascular cartridge on the stapler, or locking plastic clips (Figure 34). The pancreas is then dissected off the retroperitoneum with mono-polar scissors and a fenestrated bi-polar in a medial to lateral direction.

Figure 33. Exposure of the splenic vein following division of the pancreas.

Figure 34. Division of the splenic vein after clipping with plastic locking clips.

Figure 35. Taking down the short gastric vessels with the robotic vessel sealer.

Dissection of the Spleen and Specimen Extraction

The remaining attachments of the spleen and the short gastric vessels are divided with the vessel sealer (Figure 35). The specimen is placed in the retrieval bag and removed through the umbilical port. This port may be enlarged to permit specimen extraction. Ports and skin are closed as previously described.

ROBOTIC RIGHT HEPATECTOMY

Exposure and Ultrasound

Initial survey of the abdomen and lysis of adhesions is performed robotically eliminating the need for any laparoscopy. Ultrasound is used to delineate tumor location and anatomy.

Exposure of the porta hepatis may be obtained by placing a robotic arm below segment 4B in order to elevate it. Alternately, the gallbladder may be used for retraction once the cystic artery and duct are divided as shown previously.

Porta Hepatis Dissection

Ultrasound is used to identify the structures in the porta hepatis and aberrant anatomy, if present (Figure 36).

Figure 36. Intra operative US of the porta hepatis using the Tile Pro function.

Figure 37. Dissection of the right porta using a fenestrated grasper and monopolar scissors.

Figure 38. Encircling the right hepatic artery with a silk tie to facilitate exposure.

Figure 39. Clipping and division of the anterior branch right hepatic artery.

Figure 40. Clipping and division of the right portal vein.

The right portal pedicle is dissected in extra hepatic fashion using the mono polar scissors and fenestrated grasper (Figure 37). Once the right hepatic artery and right hepatic duct have been identified, they are encircled with 2-0 silk ties. The ties allow adequate exposure and control for clip placement and division (Figure 38). Prior to clip placement, the right hepatic artery is clamped with a bulldog clamp and ultrasound is used to confirm flow within the left hepatic artery to the left lobe. The right hepatic artery is then clipped with locking clips and divided (Figure 39).

The dissection in the porta hepatis is then continued with a fenestrated grasper and vessel sealer to identify the right portal vein. An umbilical tape is then placed around the portal vein in order to facilitate exposure. Placement of a silk tie followed by locking clips and division of the right portal vein is performed as is done for the artery (Figure 40).

The liver parenchyma is then examined for demarcation.

Parenchymal Division

Once the inflow to the right lobe has been divided, the line of parenchymal demarcation is identified. If this is not easily apparent, ultrasound may be used to identify the border between segment 4 and the right anterior sector in order to guide division.

Parenchymal division is performed using the robotic vessel sealer (Figure 41). As vessels/pedicles are identified, they are skeletonized, clipped with locking clips and divided (Figure 42). Larger branches may be stapled with a vascular load of the robotic stapler.

Hepatic Vein Division

Once a portion of parenchymal dissection has been done, the right liver is retracted medially to expose the suspensory ligaments. These are then taken down with the vessel sealer. The right coronary and triangular ligaments are taken down and the right hepatic vein

carefully dissected out. This is then encircled with a Dacron tape (Figure 43) following which it is divided with a robotic stapling device. The parenchymal dissection is then completed.

Figure 41. Parenchymal division using the robotic vessel sealer.

Figure 42. Skeletonization, clipping and division of pedicles during parenchymal transection.

Figure 43. Isolation of the right hepatic vein with Dacron tape.

Hemostasis and Specimen Removal

The cut edge of the liver is evaluated for residual bleeding and leaking biliary radicles. Biliary leakage or arterial bleeding is controlled using 4-0 monocryl. Venous oozing is controlled using a lap sponge to apply pressure followed by the application of hemostatic agents such as SurgiFlo (Ethicon, Inc. Somerville, NJ) Figure 44).

A LapSac Surgical Tissue Pouch (Cook Medical, Bloomington, IN) is introduced through the 12mm umbilical port and opened with its closed end directed towards the diaphragm. The specimen is placed within the bag and secured with a clip (Figure 45). The robot is then undocked prior to specimen removal. If the operation was performed for benign disease, the specimen may be morcellated and extracted through the umbilical port. For malignant disease the umbilical incision may be enlarged approximately 6cm in order to remove the bag with an intact specimen (Figure 46). Port sites and skin are closed as described above.

Figure 44. Application of hemostatic agents on the cut edge of the left liver.

ROBOTIC CHOLECYSTECTOMY

Adhesions are taken down by a combination of sharp and blunt dissection using the mono-polar scissors and fenestrated forceps. The liver is retracted superiorly with a Nathanson retractor. A “top-down” approach is used to dissect the gallbladder off the cystic plate. The fundus of the gallbladder or the gallbladder remnant is grasped with the fenestrated grasper and dissection carried out with a mono-polar scissor towards the neck of the gallbladder. The cystic duct and artery are then dissected, clipped with locking clips and divided. The gallbladder and any stones are placed in a robotic specimen retrieval bag and extracted through the 12 mm umbilical port. Port closure is performed as described for the other procedures.

OUTCOMES

Currently, randomized control trials (RCT) comparing robot assisted pancreatic and liver resections with laparoscopic or open resections do not exist. However, there are multiple

single or multi institutional retrospective studies, some using propensity score matching to compare specific outcomes between robotic and open approaches.

Figure 45. Placement of the right liver specimen into the specimen bag.

Figure 46. Removal of the specimen through an enlarged umbilical incision.

ROBOTIC PANCREATODUODENECTOMY OUTCOMES

A large systematic review examined data from 13 retrospective series [4]. It compared the outcomes of 738 patients who underwent robotic and open PDs between 2000 and 2016. The data showed that a robotic approach was associated with longer intra operative times but lower estimated blood loss (EBL). The learning curve to decrease rates of conversion to an open procedure was found to be 20 robotic PD's.

Overall morbidity rates were comparable between the robot and open groups in most studies. Mortality rates also did not differ between the two approaches and ranged between 1-

12.5%. Pancreatic fistula, post-operative hemorrhage and bile leak rates were not significantly different between the two groups. Delayed gastric emptying (DGE) was however, found to be lower with the robotic approach in most studies. Short-term oncologic outcomes between the two groups showed no difference in the number of lymph nodes harvested or positive margins.

A large multicenter study compared the outcomes of 211 patients from two high volume robotic PD centers and 817 patients from six high volume open PD centers [5]. This study demonstrated that the rate of clinically relevant Grade B/C pancreatic fistulas (CR-POPF) did not differ between the open (9.1%) and the robotic (13.7%) groups. Similar to most other studies, operative times were higher but EBL was lower with the robotic approach.

Other outcomes such as short-term oncologic outcomes, morbidity, 90 day mortality, length of stay and readmission rates did not differ between either operative approach.

A propensity score matched analysis to determine the effect of the robotic or open approach on the incidence of CR-POPF was published by the University of Pittsburgh.⁶ The study showed non-inferiority of the robotic to the open approach in terms of CR-POPF. Robotic PD patients had a 6.6% CR-POPF rate compared to the 11.2% fistula rate for the open PD patients. There was also no difference in 90 day mortality, 30 day readmission rates or overall complication rate between the two groups.

Outcomes have also been examined in certain specific patient populations such as those with a high BMI [7]. The robotic approach was found to be protective against CR-POPF in obese patients (classified as those with BMI > 30) undergoing PD. Obese patients who underwent a robotic PD were found to have a lower clinically relevant fistula rate of 13% compared to a 28% fistula rate in obese patients that had an open PD. Another interesting finding was that a robotic approach was protective of wound infections in morbidly obese patients undergoing robotic PD. Morbidly obese patients had a 19% wound infection rate with the robotic approach compared to 44% in those that had an open PD. There was also no difference in the mortality and Clavien 3 or greater morbidity rates between robotic and open approaches for obese patients. However, it must be noted that all the patients in this retrospective study underwent robotic PDs performed by surgeons who had surpassed the learning curve of greater than 80 cases [7].

There is a paucity of data comparing the robotic and laparoscopic approaches to PD. An NSQIP study comparing 30 day outcomes between laparoscopic and robotic PDs found that there was no difference in the 30 day morbidity or mortality between either approach [1]. However, they did find that the rates of conversion to an open procedure were higher for patients undergoing laparoscopic PD. Robotic PD was converted to an open procedure 11.3% of the time compared to a conversion rate of 26% for the laparoscopic approach. These findings are likely due to the technical advantages that the robotic platform provides over conventional laparoscopy.

Retrospective review of our experience with robotic PD at Carolinas Medical Center showed longer operative times of approximately 136 mins when compared with our open PD cohort [8]. As expected EBL was approximately 400mL lower with the robotic approach. Overall, with the robotic approach, patients had lower wound infection rates, and shorter ICU as well as hospital length of stays. The fistula rate was 7.4% for the robotic vs. 12% for the open group. This translated to an overall similar cost between the robotic and open procedures.

The total cost of robotic and open PDs at our institution were broken up into operative cost, in hospital cost and follow up charges. We found that although the operative cost was higher for the robotic approach, the shorter hospital stays associated with a minimally invasive approach and lower complication rate led to a similar overall cost when compared to an open PD.

CONCLUSION

Robot assisted surgery is a safe minimally invasive option for a complex oncologic HPB procedures. The combination of superior articulation, better optics and elimination of tremor provides technical and ergonomic advantages over conventional laparoscopy. These enable the surgeon to perform a safe resection and when required, a complex reconstruction with lower rates of conversion to an open procedure when compared to laparoscopy [1]. At high volume centers, once the learning curve has been surpassed, complex robotic HPB procedures such as robotic PD has been shown to be non-inferior to open PD in terms of POPF development and other peri-operative outcomes [3, 5, 8]. The higher operative cost of the procedure may be offset by lower hospital length of stays associated with a minimally invasive approach. However, more robust data in the form of a randomized controlled trial and other cost benefit studies are warranted.

Chapter 252

ROBOTIC-ASSISTED BARIATRIC SURGERY

Matthew Sharbaugh, MD and Christopher You, MD

¹MedStar Washington Hospital Center, Washington, DC, US

²Minimally Invasive and Bariatric Surgery, Robotic Surgery Program,
MedStar Franklin Square Medical Center, Baltimore, MD, US

INTRODUCTION

Robotic surgery combines the best of open surgery and laparoscopic surgery. With open surgery, the surgeon utilizes the dexterity of one's hands. With laparoscopic surgery, the surgeon takes advantage of the improved vision and magnification. Robotic surgery, in its present form, brings this dexterity and vision together in a way that mitigates the loss of the advantages of open and/or laparoscopic approaches, such as tactile sensation, by providing 3D vision, enhanced vision through fluorescence imaging, and superior ergonomics. Robotic surgery also provides a platform to take surgery even further with computer-assisted surgery that will incorporate enhanced information overlays, real-time remote collaborative surgery, and new paradigms to dissect and reconstruct.

Bariatric surgery adopted laparoscopic techniques and saw dramatic improvements in patient outcomes. Advances in energy devices for dissection and stapling platforms for reconstruction has made laparoscopic surgery the de facto choice for a majority of bariatric surgeons today. They have also prevented bariatric surgeons from adopting robotic surgery because of nascent robotic energy and stapling devices. However, energy and stapling from the current robotic platform is improving and it is expected that an emerging competitive robotic stapling platform will rival the current laparoscopic endostapling companies. Robotic energy devices will also continue to advance next generation devices in development. In addition, companies with expertise in energy and stapling for laparoscopic surgery will be developing computer-assisted surgical platforms within the next several years.

With the advent of a robotic platform with viable energy and stapling devices, increased competition within the robotic surgery space, and the continuing evolution of bariatric surgical procedures that require energy, stapling, and suturing, bariatric surgeons are looking to the robotic platform with increasing interest. However, because of the excellent outcomes

already achieved, how much can be improved by robotic surgery? The rationale for robotic surgery as it “comes of age” for bariatric surgery is not just an outcomes issue, but a cost issue as well. And the cost equation must not only include supply costs but also additional costs due to complications, costs due to time off work for patients, costs due to workplace injury for surgeons, and even costs due to loss and recruitment of surgeons. Further, increasing competition within the industry should help advance instrumentation and reduce costs. We are confident when all these factors are taken into account, robotic surgery will become the dominant approach.

GENERAL CONSIDERATIONS

Preoperative Planning

In preparing patients for robotic surgery, there are no special considerations to prepare a patient for robotic bariatric surgery that is any different from laparoscopic bariatric surgery.

Peripheral IV Access

When we initially started doing gastric bypass on the Si system (Da Vinci, Intuitive Surgical, Sunnyvale, CA), a standard practice for us was to place an IV in each upper extremity. This was because the Si patient cart column would be at the head of the OR table impeding access to the head and to the opposite arm. Since switching to the Xi system (Da Vinci, Intuitive Surgical, Sunnyvale, CA), this practice has continued but is really a vestige of the days we used the Si. While less necessary, with a mixed platform hospital such as ours with Si and Xi systems, it is better to continue this practice for patients undergoing procedures with both Si and Xi.

Robotic System Component Positioning

In regards to the Xi system, positioning the system in relation to the patient is very easy. The Xi patient cart stays in the same place relative to the operating table. It is on the patient’s left, backed to the wall. Whether the procedure is bariatric, general surgery, urogynecology, colorectal, or gynecologic oncology, the robot stays in the same place and is wheeled in from the patient’s left. The vision cart is placed on the left side of the patient, far enough past the feet to allow for the scrubbed personnel to pass between the vision cart and the patient cart without the risk of contamination. The surgeon console is placed in the corner of the room away from traffic. Access to the patient’s upper body and head is not compromised with the Xi system (Figure 1).

Figure 1. Intuitive Surgical da Vinci Xi robot showing access to the patient’s upper body for anesthesia.

Figure 2. Si system undocked.

Figure 3. Si system docked.

With the Si system, positioning of the system is more difficult because of the way that the patient cart has to be moved when docking. We have laminated cards in the room to delineate placement of the patient cart, vision cart, and surgeon console for the undocked and docked states (Figures 2 & 3). Additional room cards have been made for the different surgical disciplines.

Patient Positioning

We current utilize a Skytron bed (Skytron, LLC., Grand Rapids, MI) with the split leg attachment and the ability to slide, in addition to the standard bed functions. Gel padding is utilized for areas prone to pressure sores. A hover mat is in place prior to the patient laying down to assist in patient transfer after surgery is complete. A foot plate is placed on the bed and a strap is placed over the thighs.

A Bair Hugger (3M, Mapplewood, MN) can be placed over the upper chest and arms or over the lower legs.

For induction, anesthesia often uses a ramp to elevate the upper torso. This *must* be removed prior to operating and the arms should not be hyperextended to prevent a brachial plexus injury. In addition, the ramp decreases the working space in the upper abdomen which may make cases with copious visceral fat very difficult. We typically have the arms out at 45-60 degrees in relation to the abdomen.

Figure 4. Port placement for robotic gastric bypass (Xi).

For liver retraction, a Nathanson liver retractor is attached to an Iron Intern that is attached to the bedrail just under the patient's right arm. A critical detail to avoid collisions

with the robotic arms is to angle the vertical pole towards the head. When the patient is in reverse Trendelenberg, the vertical portion of the Iron Intern is then perpendicular to the floor. In addition, the horizontal portion of the vertical pole should be as close to the patient's body as possible with putting any pressure on the patient's body (Figure 4).

Reverse Trendelenberg is steep for sleeve gastrectomy but for gastric bypass, the amount of reverse Trendelenberg is less than what we do for laparoscopic gastric bypass.

ROBOTIC GASTRIC BYPASS

Technique

There are several salient features of this procedure that must be considered. First, gastric bypass is multi-quadrant surgery, especially when additional procedures must be performed, such as adhesiolysis in the lower abdomen and pelvis, cholecystectomy, ventral hernia repair, and hiatal hernia repair. An analysis of procedures that we have performed showed that one-third of our bariatric surgeries required at least one of these additional procedures. The robot lends itself very well to these situations.

Second, energy is a vital tool in the deconstruction of anatomy. The best energy tool will be able to incorporate the ability to dissect, retract, and seal. It will also have maximum mobility, including reach and wristed motion. For instance, the vessel sealer on the Xi platform is very good at dissecting the tissue layers at the left crus while at the same time using the shaft of the instrument proximal to the point of flexion to retract fat away from the area of dissection. While this may often be momentary retraction before the fat slips back into view, there is often enough time to accomplish the maneuver.

Figure 5. Xi robot docked for gastric bypass.

Figure 6. Division of the epiphrenic fat pad.

Figure 7. Lesser curve dissection.

Finally, formation and reconstruction are key aspects of the gastric bypass—formation of the gastric pouch and reconstruction of gastric continuity through the gastrojejunostomy and the jejunajejunostomy. The main techniques at our disposal are suturing and stapling. Robotics allows us to take an uncompromising approach, optimizing the use of suturing and stapling to minimize complications.

There is no doubt that formation of the gastric pouch is best done with endostapling. Currently, we utilize the Endowrist robotic stapling platform on the Xi. To create the gastric pouch, we first divide the epiphrenic fat pad to clearly identify the angle of His (Figure 6). The stomach is partially dissected off the left crus as well. We then measure a point 6 cm below the GE junction along the lesser curve. We preserve the lesser curve vessels and vagus nerves by dissecting along the stomach wall into the lesser sac (Figure 7). Sometimes we will have to open pars flaccida to introduce air into the lesser sac which aids in identification of the correct dissection plane. Robotics provides superior visualization and manipulation of tissue to minimize the dissection area and control for bleeding. For the horizontal staple line

from the lesser curve, we use a green 45 mm staple load with Peri-Strips (Figure 8; Ethicon, Inc., Somerville, NJ). The Peri-Strips serve as an anchor for the posterior layer of sutures for the gastrojejunostomy. After completing this staple line, we then dissect any adhesions posterior to the stomach wall towards the angle of His. We will dissect posterior to the stomach all the way to the left crus and find the dissection plane we established from the anterior approach. In dissecting this space, we rarely have to take down vessels to the stomach. There is a distinct plane that is easily seen with 3D visualization between the vessels to the stomach and the peripancreatic fat that opens up to reveal more of the left crus. A vertical staple line using blue loads without buttressing is then created from the end of the horizontal staple line up to the angle of His. This is loosely formed around a 32 French Ewald tube. The ability of the robotic stapler to move left to right in a 108 degree arc and up and down in a 54 degree arc allows one to place the stapler to the tissue rather than distorting the tissue towards the stapler. This is especially useful when creating the vertical staple line near the left crus (Figure 9). If the patient has a history of anticoagulation use, then we will use green loads with Peri-Strips for the vertical staple lines of the pouch.

Figure 8. Gastric pouch horizontal staple line.

Figure 9. Vertical staple line of gastric pouch.

Figure 10. Small bowel management.

Figure 11. Transecting jejunum.

Figure 12. Dividing jejunal arcade.

Figure 13. Mesenteric dissection plane.

In reconstructing gastric continuity, the jejunojejunostomy is constructed on the left side of the mesenteric axis in an anti-peristaltic fashion. The biliopancreatic limb is 60 cm long from the ligament of Treitz. A crucial skill when performing a robotic gastric bypass, without the interconnected bed to change the angle of the bed and arms while docked, is managing the bowel. When counting off the biliopancreatic limb, the proximal bowel is pushed towards the patient's left (Figure 10). The transection point of the bowel is positioned towards the patient's right in a gentle loop. A single firing of the Endowrist 45 mm white load from the patient's right is used to divide the bowel at this point (Figure 11). We then carefully divide the mesentery towards the root being careful not to divide the jejunal or straight arteries, and dividing the arcade as needed to ensure adequate length of the Roux limb to reach the gastric pouch (Figure 12). A distinct plane can be developed in the mesenteric fat between the jejunal arteries which is quite remarkable to note under 3D vision that cannot be appreciated via open or laparoscopic approaches (Figure 13). The end of the biliopancreatic limb is lifted towards the abdominal wall and then the Roux limb is tucked above the end of the biliopancreatic limb and to the patient's left as it is counted off to 150 cm. After the appropriate point for the jejunojejunostomy is identified and placed next to the biliopancreatic limb, the small bowel is "unwound" from its position behind the end of the biliopancreatic limb. Enterotomies are made by using the closed Monopolar Curved Scissors using the Cut function (Setting on Dry Cut, Effect Level 2). The openings are kept as small as possible. One of the benefits of the Endowrist stapler, especially on the cartridge side, is that tissue does not snag against the stapler when inserting the anvil or cartridge. A white cartridge on the Endowrist 45 mm stapler is inserted from the patient's right. The anvil is passed first and goes in the Roux/Common channel side. The anvil goes through the enterotomy and points distally in relation to the small bowel. The cartridge side is passed through the enterotomy on the end of the biliopancreatic limb and points proximally, or retrograde. The bowel is positioned parallel to each other according to the "grain" of the bowel which is easily seen with 3D vision. The stapler is closed and fired (Figure 14). The common enterotomy is closed in a single running layer of 2-0 Vicryl (Ethicon, Inc., Somerville, NJ) sutures. We take care to make sure that the ends of the staple lines on either side of the common enterotomy are buried with the 2-0 Vicryl running suture as a single layer (Figure 15). In fact, the ends of the staple line actually lie below the suture line and isn't incorporated into the sutures. To date, we have not had an

obstruction or leak using this technique. Furthermore, when we have returned to the abdomen of a patient we performed a gastric bypass, we do not see dilation of the jejunojejunostomy that is seen with the triple-plus staple technique. The mesenteric defect is closed using 2-0 Ethibond (Ethicon, Inc., Somerville, NJ) in running fashion (Figure 16). Here, we have found that when placing sutures on the side where the mesentery is continuous (Roux limb/common channel), suturing with the needle parallel to the vessels going from the bowel towards the root of the mesentery results in the least chance of bleeding. When suturing on the cut end of the mesentery (biliopancreatic limb), we suture perpendicular to the vessels taking the peritoneum on either side of the mesentery without actually going through the mesentery.

Figure 14. Stapling to create the jejunojejunostomy.

Figure 15. Burying staple line corner on jejunojejunostomy.

The Roux limb is brought up to the gastric pouch in an antecolic fashion. There is a space where bowel can herniate between the transverse colon mesentery and the small bowel mesentery and we close this space with a running 2-0 Vicryl to induce some scarring. When lifting up the transverse colon mesentery up and down away from the small bowel mesentery, one can see the inflection point between the two sides. This is the starting point for our suture. We then let go of the transverse colon and wherever the underside of the transverse colon

mesentery opposes the root of the mesentery of the Roux limb marks the end point of our suture. We then lift the transverse colon mesentery back up and start placing the running suture. As we run the suture and tighten it, we lower the transverse colon to allow the two mesenteries to come together (Figure 17).

Figure 16. Mesenteric closure.

Figure 17. Closing the retro Roux space.

In bringing up the Roux limb, the end points towards the left of the patient. In other words, the Roux limb is oriented in a counter-clockwise fashion when looking down at the patient. Care is taken to make sure that the Roux limb is not twisted around the mesentery. The debate continues about whether a circular-stapled, linear-stapled, or hand-sewn anastomosis is superior for the gastrojejunostomy. Leak rates, structure rates, ulcer rates, and other complications can vary from one method to another depending on the study. Perhaps more than which method is better, the better question is what rate for each complication is the benchmark we should hope to attain with whichever method we adopt. Maybe the best outcomes are by matching a particular surgeon with a particular methodology, mostly by the strengths and weaknesses of the surgeon. Perhaps we will find that the robotic platform will allow for more surgeons to have lower complication rates. With more than 600 robotic gastric

bypasses, our leak rate is zero, stricture rate is less than 1%, and ulcer rate is less than 2%. For us, we feel that the robotic approach allows us to achieve the best outcomes we possibly can. Constant evaluation and assessment allows us to connect our methodology to our outcomes as individual surgeons. In other words, intentional experience gets to a point where we can predict the complications based on patient factors, what we saw during surgery, and how we did in surgery.

After orienting the end of the Roux limb to the horizontal staple line of the gastric pouch, we use an undyed 2-0 Vicryl on an SH needle cut to 8 inches to first get a bite through the stapled corner of the gastric pouch, through the Peri-Strip. Using the left hand, we then suture a couple centimeters away from the end of the Roux limb about 5 mm posterior to the anti-mesenteric border. A surgeon's knot is formed and when cinching down this knot, we make sure that the Roux limb is on the anterior aspect of the staple line. We put a total of four square knots, leaving the free end of the suture a couple centimeters long, and then run the 2-0 Vicryl, advancing 5 mm and starting about 5 mm away from the staple line on the anterior side of the pouch. The needle is brought out through the Peri-Strip on the posterior side between the two staple lines. Every suture through the gastric pouch is done with the right hand while every suture through the Roux limb is done with the left hand. When cinching down this suture line, we make sure the bowel is anterior to the staple line. Once we reach the medial aspect of the gastric pouch, the suture is tied to itself using four square knots (Figure 18).

To make the gastrotomy and the enterotomy, we use the Monopolar Curved Scissors and the "Cut" function (Setting on Dry Cut, Effect Level 2). We open the scissors and using cautery mark out where our gastrotomy will be on the serosa. The "Cut" function is used to go through the layers but if a vessel is seen, then switch to the "Coag" function to control the vessel and go back to the "Cut" function. Once we reach the stomach mucosa from the outside, we make a final small hole using cautery to get into the lumen and then use the scissors to actually open this layer to the extent of the gastrotomy. Opening the mucosa should be bloodless if the vessels outside of the mucosal layers have been controlled. The resulting opening is about 12 mm across (Figure 19).

For the enterotomy, the process is similar, however, the mucosal layer is more folded, due to the plicae circulares. You have to make sure that the entire mucosal layer is divided for the extent of the enterotomy. A double-armed suture is fashioned by taking two 2-0 dyed Vicryl sutures on SH needles cut to seven inches and taking the free ends to make a two-strand overhand knot. We then backhand the first bite through the small bowel side in the middle of the upper side of the opening. We then take the next bite with this suture through the middle of the stomach on the lower side of the opening. Continue running this suture to the left (patient's right). The key here is to advance the suture sufficiently. To ensure this, we simply place the next suture between the corner of the opening and the middle of the opening, again backhanding this through the small bowel and then the stomach. Pass the suture two more times, on either side of the corner of the opening. This suture is cinched down; then take the other end of the double arm and run it to the right in a forehand direction using the left hand, making sure that we advance far enough with each bite using the same technique. After the posterior row of this inner layer is complete (Figure 20), continue the anterior row by advancing the sutures on either side toward the middle. Before cinching down these sutures together which should now be on opposing sides of the opening, the anesthetist will advance

the 32 French Ewald tube gently through the gastrojejunostomy. The suture is snugged up around the Ewald and then tied down (Figure 21).

For the outer anterior layer, run an undyed Vicryl on an SH needle cut to eight inches from the medial aspect of the gastrojejunostomy and tie it to the free end of the posterior outer row that was left long. This completes the gastrojejunostomy (Figure 22). The end of the Ewald tube is drawn back into the pouch and with the small bowel compressed just distal to the gastrojejunostomy, 30 cc of a methylene blue/saline mixture is injected under direct visualization.

Outcomes

Robotic assisted surgery was FDA approved in 2000 and the first robotic assisted Roux-en-Y Gastric Bypass (RYGB) was reported in the literature in 2003 [1]. Since that time the robotic platform has seen increasing use in all aspects of bariatric surgery, from the vertical sleeve gastrectomy (VSG) to revisional bariatric surgery. The most common robotic surgery described in the literature is the RYGB. The reported techniques used in the RYGB vary widely across the literature. The technique described most often is the robotic assisted RYGB, where the stapling is done laparoscopically through an assistant port. The totally robotic RYGB is gaining popularity. The approach creates the gastrojejunostomy via a hand-sewn two layer closure.

Anastomotic leak is rare after gastric bypass surgery but remains the most feared complication as it can be fatal. The robotic platform allows for more accurate suture placement with improved visualization and handling leading to a lower leak rate. A study by Snyder et al. showed a significant reduction in leak rate when using the robotic platform [2]. There were no mortalities in this study. In another study by Buchs et al., 777 patients were reviewed. Those patients undergoing robotic gastric bypass surgery had a significantly lower leak rate of 0.3% when compared to a similar laparoscopic cohort (3.6%) [3]. There are data to the contrary. A report published by Benizri showed a higher leak rate in robotic gastric bypass compared to a laparoscopic cohort (3% vs 0%) [4]. A larger review study encompassing 19 studies did not show an overall difference in leak rate between robotic and laparoscopic gastric bypass. It did, however, support a lower anastomotic leak rate in totally robotic gastric bypass surgery (OR 0.22) when compared to laparoscopic stapled gastric bypass [5]. The robotic RYGB decreases leak rate, the most morbid of post-operative complications.

Anastomotic stricture can present with nausea, pain, and dysphagia. These symptoms are debilitating as patients cannot tolerate oral intake. Strictures require endoscopy and balloon dilation to abate these symptoms. There has been much debate comparing technique and stricture rate in gastric bypass surgery. Maker et al. published a pooled analysis of 1686 patients and found that there was a statistically significant reduction in anastomotic stricture rate in robotic RYGB when compared to the laparoscopic approach [6]. Benizri found the opposite. In this study a 7% stricture rate was noted in RYGB surgeries performed robotically when compared to 0% when done laparoscopically. In a series of 143 patients, Hagen et al. confirmed similar findings to Maker [7]. They reported a 6.8% stricture rate when RYGB was done laparoscopically and 0% rate when done robotically. Li's meta-analysis showed a trend toward lower stricture rates (OR 0.8) favoring the robotic approach; however, this was not statistically significant [5]. Economopoulos' review did not find an overall difference in anastomotic stricture rate but did show a statistically lower stricture rate in robotic RYGB surgery where the gastrojejunostomy was hand sewn [8]. The robotic hand sewn RYGB decreases stricture rate and the associated morbidity.

Traditional length of stay after bariatric surgery is relatively short. The majority of patients are discharged within a few days. The robotic approach aids in decreasing this already short length of stay. The robotic trocar is designed to work as a fulcrum which decreases torque, stress, and strain on the abdominal wall and creates less pain. Less pain can lead to earlier mobilization and oral intake. Ayloo's robotic RYGB patients left the hospital on average one day before a similar laparoscopic cohort of patients [9]. A larger review by

Economopoulos did not show an overall difference in length of stay when comparing robotic and laparoscopic RYGB but subgroup analysis did favor shorter length of stay in the robotically assisted gastric bypass patients [8].

Conversion to open operation is rare in bariatric surgery. Difficult anatomy, poor visualization and dense intra-abdominal adhesions are potential reasons for conversion to open operation. There is no higher likelihood of conversion to open procedure when the robotic technique is used for gastric bypass surgery [5]. Economopoulos' review did not find an overall difference in rates of conversion to open surgery. Subgroup analysis did however find a subset of patients who underwent robotically assisted gastric bypass that had slightly lower reoperation rates [8].

A reported disadvantage to robotic surgery is an increased operating time and the associated costs. The increase in operating room time is contributed to time spent docking and undocking the robotic console and an increase in the use of hand sewn techniques. The hand sewn techniques may take longer than stapled techniques. The tradeoff for increased operative time is decreased complication rates. Not all studies show a longer operating time for robotic surgery, however. Ayloo published a study that showed robotic surgery was actually 27 minutes faster when comparing robotic and laparoscopic RYGB [9]. Fourman, in contrast, found that the laparoscopic technique was 19 minutes faster than robotic RYGB [10]. Economopoulos' meta-analysis did not find a significant difference in overall operating time but subgroup analysis favored the stapled laparoscopic technique [8].

The Intuitive Surgical da Vinci robotic surgical system requires a large upfront investment of up to two million dollars [7]. In addition there is a substantial cost to yearly maintenance. In today's cost conscious environment this large investment has led many to publish negative reviews on the increased cost of robotic surgery. Much of this data was written about hybrid operations where the anastomosis is still done with a laparoscopic stapler. The laparoscopic staplers and cartridge reloads greatly increase the cost of bariatric operations. Hagen showed similar operating room costs when the anastomosis is created with a hand sewn technique and not the stapler [7]. In addition there is a growing body of evidence that the improved optics and maneuverability in a tight space of the robotic platform can lead to lower leak rates [2]. One anastomotic leak is estimated to cost 400,000 dollars if the patient requires ICU admission for sepsis [11]. The reduction of stapler costs and decreased leak rate make the robotic RYGB with a hand-sewn gastrojejunostomy cost effective.

ROBOTIC VERTICAL SLEEVE GASTRECTOMY

Technique

Our current sleeve technique utilizes the Standard Clamp by Standard Bariatrics (Figure 23; Blue Ash, OH). We use four ports with a fifth incision for the Nathanson liver retractor.

The idea behind the Standard Clamp is to employ a laparoscopic device designed to clamp the entire length of the stomach thereby enabling surgeons to plan and hold the staple line prior to division. IT also protects key areas such as the gastroesophageal junction, incisura angularis, and pylorus. The surgeon can create a predictable size, shape, and volume sleeve each and every time.”

After positioning the patient as described earlier in the chapter, we access the abdomen using an optical eight mm robotic trocar on the patient's left side along the left anterior axillary line about 22 cm away from the midline. Another eight mm robotic trocar for the camera is placed along the left mid-clavicular line, 12 cm away from midline. The 12 mm robotic staple port is placed at the midline or to the left of midline depending on the location of the pylorus. Before placing the last trocar, a 12 mm non-robotic trocar, a line from the angle of His through a point on the greater curve five cm from the pylorus is projected onto the abdominal wall. This point on the abdominal wall is where the Standard Clamp will go through. Because the Standard Clamp is straight without any flexion points, it is important to have a location through the abdominal wall that will then allow for aligning the clamp to the appropriate landmarks of the stomach, i.e., angle of His, incisura, and five cm from the pylorus. A 12 mm laparoscopic port is placed here. An eight mm robotic trocar is then telescoped within this 12 mm laparoscopic port until the Standard Clamp is needed. The implication of this port placement is to have two instruments for the left hand since stapling is performed with the left hand. We have found this to be the optimal configuration. Finally, a Nathanson liver retractor is placed through the abdominal wall just below the xiphoid process.

To begin the dissection, we choose a point about two-thirds distal on the greater curve from the angle of His. We elevate this portion of the stomach and then bluntly dissect just medial (or superior) to the fat over what appears to be the stomach. Careful and repeated spreading of the vessel sealer allows one to enter the lesser sac without blood loss (Figure 24). Because the vessel sealer is wristed, it is easy to take this dissection distally towards the pylorus and proximally towards the spleen and angle of His.

Figure 23. Standard clamp.

Figure 24. Beginning the greater curve dissection.

When taking this dissection distally, it is important to take down the adhesions and attachments behind the antrum and lesser curve of the stomach (Figure 25). The lesser curve

of the stomach can be mobilized off the pancreas all the way up to the left gastric artery. There should be no significant vessels to mobilize the stomach, otherwise the correct plane has not been found.

Figure 25. Distal extent of posterior stomach dissection.

Figure 26. Dissecting the fundus from a posterior approach.

Figure 27. Dissecting the fundus from a medial approach.

Figure 28. Dissecting between the stomach and pancreas.

Figure 29. Stomach dissected off of left crus.

Figure 30. Standard clamp in place.

Figure 31. Completed sleeve.

Taking the dissection proximally, when we get to the apex of the fundus, we lift the fundus upwards and laterally (Figure 26). Dissection of the medial aspect of the fundus back down to the angle of His is done from *behind* (i.e., posterior to) the stomach. In some instances, instead of continuing from a lateral approach, dissect from a medial approach starting over the left crus (Figure 27). After the greater curve is completely dissected, we expose more of the left crus inferiorly. This is where the robotic system shines because you can see the distinct plane between the fat and vessels of the stomach on the medial aspect of the left crus compared to the peripancreatic fat on the lateral aspect of the left crus (Figure 28). By exposing the left crus in this plane, very few if any vessels need to be crossed and there is better mobilization of the stomach (Figure 29). When the dissection is complete, the lesser curve vessels are intact, the lateral stomach is completely mobilized with the left crus exposed, and the only point of attachment on the greater curve is the gastrocolic ligament for the last five cm of the stomach.

With the dissection complete, the 18 French orogastric tube is placed along the lesser curve. One must take into account the width of the Standard Clamp and the fact that stapling occurs lateral to the “clamp”. Together, the 18 French orogastric tube and the one cm wide Standard Clamp results in a sleeve that is about 40 to 44 Fr. The greater curve is marked one centimeter from the angle of His. A mark is placed perpendicular to the lesser curve three cm away. Finally, a mark is placed six cm away from the pylorus. The number 1 robotic arm is undocked, the eight mm robotic trocar is removed from the 12 mm laparoscopic port and the Standard Clamp is introduced. The two Cadieere graspers are in robotic arms 1 and 4. The Standard Clamp is opened, and the stomach is then placed between the jaws of the standard clamp. The stomach is retracted laterally and once the mark at the angle of His is seen and the clamp is snug against the orogastric tube, the Standard Clamp is closed until the first click is heard. The stomach is worked through the Standard Clamp towards the incisura and once the mark at the incisura is visualized and the clamp is snug against the orogastric tube, the Standard Clamp is closed until the second click is heard. Finally, once the third and final mark on the greater curve is visualized, the Standard Clamp is closed (Figure 30).

Utilizing the SureForm 60 mm stapler, stapling occurs lateral to the Standard Clamp. Currently, the first cartridge of the stapler is a green load. The last three cartridges are

usually blue loads. Occasionally, the last cartridge is a white cartridge. Other times, a fifth cartridge is required to complete the sleeve (Figure 31).

There are multiple benefits to the Standard Clamp. First, a reproducible sleeve is possible using the anatomic landmarks. It does require a more precise dissection along the medial and posterior aspects of the stomach, especially between the fundus and the left crus as well as between the antrum and the transverse colon mesentery and pancreas. Second, fewer staple loads are used. Using the Standard Clamp has resulted in three to four less loads per case of the SureForm 60 mm compared to the Endowrist 45. Finally, because there is less extrusion of the tissues when clamping and firing the stapler, the staple line is straighter. Along with the benefit of consistent placement and straighter staple lines, we have abandoned using Peri-Strips on the first three fires of the stapler. These changes have resulted in a cost per case that is competitive with non-robotic endostaplers.

Outcomes

There is a paucity of data on the robotic sleeve gastrectomy compared to robotic RYGB. The data available to date supports the robotic platform as feasible and safe. One reported advantage of using the robot for vertical sleeve gastrectomy is to oversee the staple line. This technique is surgeon-dependent. The wristed instruments and 3-D magnification make this step more feasible and accurate. However, the benefit of staple line reinforcement leads to longer operating room times and remains a highly debated topic today. The most recent American Society for Metabolic and Bariatric Surgery (ASMBS) data on staple line reinforcement in laparoscopic VSG suggests staple line reinforcement of any kind leads to higher leak rate [12].

Leak and bleeding are the two major causes of morbidity and mortality after sleeve gastrectomy. The leak and bleeding rates are not significantly different between robotic and laparoscopic surgery. Ayloo did not have any patients with staple like leak in a study of 69 patients [13]. Magouliotis' meta-analysis of 16 studies also found no significant difference in leak rate between laparoscopic and robotic techniques [14]. Postoperative bleeding was not statistically different in either study [13, 14].

The VSG operation is designed in a way to limit oral intake. The nature of this restrictive operation lends itself to a very real complication of post-operative stricture. As in RYGB stricturing of the gastric sleeve leads to debilitating oral intolerance and repeated dilations. Romero compared 134 robotic sleeve gastrectomies to a similar laparoscopic cohort and found no difference in stricture rate between the two techniques [15].

Most surgeons observe VSG patients one night in the hospital. These patients need hydration and confirmation that they can tolerate oral intake of liquids. The length of stay is very short. However, in the review article by Magouliotis, length of stay was significantly longer in the robotic VSG group [14]. Data to the contrary was published by Elli where robotic VSG patients had a length of stay 0.5 days shorter [16]. It is unclear why there would be a difference in the length of stay after VSG based on operative technique.

The robotic and laparoscopic RYGB have both excellent and durable long term weight loss. The mean decrease in BMI at one year is 16 [13]. There is no difference between robotic and laparoscopic VSG in excess weight lost at 12 months. Both techniques had considerable

excess weight loss of up to 68% [14] and should be considered when offering surgery to combat medically complicated obesity.

Magouliotis and Ayloo showed a longer operating time for patients undergoing a robotic sleeve gastrectomy when compared to laparoscopic surgery by 20 minutes [13, 14]. Oversewing the staple line is likely to contribute to this difference [13] in some series and in others the docking time made the significant difference [17]. Romero found the operating time to be 12 minutes longer for robotic sleeve gastrectomy when compared to laparoscopic [15]. In contrast, there is a subset of super obese patients with a BMI > 50 where operative time is significantly shorter for robotic sleeve gastrectomy [16]. The large fatty sheet of greater omentum and a smaller working space can limit access to the hiatus and left crus causing difficulty during laparoscopic VSG. The robotic platform allows improved visualization and maneuverability in this area which decreases operative time in the super obese cohort.

A reported disadvantage of robotic VSG is overall cost. As in robotic RYGB, there is a substantial cost to purchasing the robotic platform and yearly maintenance fee. There are few studies reporting the cost of robotic VSG. Magouliotis et al. found increased costs in four out of five studies in their review. Yet they were unable to perform a meta-analysis due to lack of consistent data present in the literature [14]. Diamantis suggested the robotic approach is approximately 400 Euros more expensive [17].

The above data shows the robotic VSG is safe and feasible and provides durable weight loss. The robotic approach is durable and leads to excellent weight loss that is comparable to the laparoscopic approach. The benefits of reduction in anastomotic leak, seen with robotic RYGB, are not present in robotic VSG but the subset of super morbidly obese patients have a shorter length of stay and mean operating room time but at a higher cost. Both of these advantages are likely due to the ease of operating around the diaphragmatic hiatus on the robotic platform.

ROBOTIC REVISIONAL SURGERY

Technique

Because of the varying circumstances for revision, anatomy, deconstruction and reconstruction, it is hard to provide a step-by-step guide to how to perform revisional surgery. Suffice it to say that there is no better way to do revisional surgery than with the robot. The ability to find or make planes, delineate anatomy, and evaluate tissue viability make revisions a pleasant challenge.

One of the first challenges for revisional surgery is getting access to the peritoneal cavity. We perform the minimum amount of adhesiolysis to get at least three robotic trocars into the abdominal cavity. Once this is achieved, then the rest of the adhesiolysis can be performed robotically which can save more time and result in a less bloody field than trying to continue laparoscopically or convert to open. We dissect sharply as much as possible which requires taking the time to find the right planes. Vessels that will bleed when cut are taken care of with cautery before transection, whenever possible, unless they are adjacent or near to bowel. Bipolar energy can be used in these cases if necessary. Additional trocars are placed as

allowable. Liver retractors may not always be needed as scarring often keeps the left lateral segment of the liver elevated off the stomach, especially when adhesions between the liver and stomach are taken down.

After most of the adhesiolysis is done, the next step is to identify the right crus. Access to the left crus is often impeded by scarring so the better landmark to approach first is the right crus. Pars flaccida may already be opened up but in other cases it is necessary to open up pars flaccida. Once the right crus has been identified, one can proceed with dissecting out the hiatus for a hiatal hernia. Alternatively, one can dissect below the level of the left gastric artery posterior to the stomach which can be helpful when forming the gastric pouch. This maneuver may also be helpful to getting around the stomach from behind on a previous sleeve to dissect out an obscured staple line.

During the dissection, care has to be taken to minimize compromising any vessels until the full anatomy is known. In the case of previous vertical banded gastroplasty or non-divided gastric bypass, it is also important to know where the previous staple lines are and make sure they are accounted for appropriately with subsequent firings of the endostapler. It is always prudent to perform a new lateral vertical staple line that is medial to the old staples lines whenever possible. Firefly imaging can be used as an adjunct in these cases to make sure the blood flow to the gastric pouch has not been compromised.

In performing a revision of the gastrojejunostomy due to ulceration, most cases are associated with a gastric pouch that is too large. In these instances, it is straightforward for the horizontal staple line to be above the gastrojejunostomy without fear of making the gastric pouch too small. However, there have been a couple occasions where the gastric pouch was a perfect size and using an endostapler above the gastrojejunostomy would have made the gastric pouch too small. In this situation, devascularize the small bowel segment that will be coming out first. With blood flow stopped to this portion of the small bowel, a demarcation line will promptly appear between the stomach and the small bowel. Sharp dissection and cautery are then used to divide the gastrojejunostomy at the demarcation line. Subsequently, proceed with the gastrojejunostomy as described in the gastric bypass section.

Outcomes

Surgery is the most effective treatment for obesity. There is a small subset of patients that do not lose the expected weight, have weight regain, or chronic symptomatology that requires revisional surgery. The benefits of operating on the robotic system have led to increased enthusiasm for revisional robotic bariatric surgery. Snyder et al. reviewed 99 patients undergoing revisional bariatric surgery performed on the Intuitive da Vinci robotic surgical system [22]. The revisions were durable leading to a decrease in average BMI from 44 to 29 kg/m² at three years. This patient population had a high complication rate (24%) and elevated readmission rate (17%) which is similar to laparoscopic revisional surgery [23]. Buchs et al. compared robotic to laparoscopic revisional bariatric procedures [24]. They found fewer complications in the robotic group. In addition they showed a shorter length of stay but increased operating time. At the present time the robotic platform has a role in these complex reoperative bariatric surgeries but the data remains limited.

DUODENAL SWITCH

The authors currently do not perform duodenal switch (DS) procedures. In the near future, we will begin performing the loop DS. The loop DS is a modification of the DS which only requires one anastomosis between the duodenum and the ileum, in an end-to-side fashion. While currently not on the approved procedures list of ASMBS and not covered by insurance, studies show increased weight loss without the morbidity of traditional duodenal switch. Loop DS lends itself particularly well to a robotic approach due to patient factors such as high BMI, the multi-quadrant nature of the procedure, and the benefits of using a hand-sewn technique for the duodeno-ileostomy. The loop DS will provide the benefits of a bypass type operation, preservation of the pylorus, and increased weight loss, while also decreasing the complexity of surgery compared to procedures requiring two anastomoses. Additional benefits include the ability to use NSAIDS after surgery and less reservations to provide a bypass-type operation for patients at high-risk of nicotine recidivism.

Duodenal switch represents only a small minority of operations performed today for obesity (<1%) [18]. Recently, there has been a renewed interest in the DS with the advent of the robotic surgery platform. Sudan et al. reviewed 59 patients who underwent robotic DS. No patients in their series had an anastomotic leak or bleeding complication (21). There were no mortalities and the complication rate was low. The operative time was on average 306 minutes. The DS is technically challenging but may have a role in the super obese. The robotic approach is safe and feasible but more data is needed for further review of the role of robotic assisted DS.

CONCLUSION

As surgeons, we need to evaluate not only clinical factors but also financial factors. In considering financial factors, we should not just listen to what administrators say, but see for ourselves what the true cost of surgery is. That is, we need to account for costs not only for the clinical care of the patient, but also costs due to patients being out of work, costs due to workplace injury for surgeons, the cost of a surgeon having to retire earlier than expected, and the cost to recruit and replace surgeons.

When considering clinical factors, the potential for technology to make us better surgeons is here and will continue to improve. Surgeons need to critically evaluate for themselves the different tools and techniques available along with an assessment of their own strengths and weaknesses to decide how to approach each case in their surgical repertoire. Fortunately with the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program, bariatric surgeons can constantly evaluate and improve based on their own clinical data. Finally, increasing competition and continuing development of computer-assisted surgery should help accelerate the field over the next decade.

INTRODUCTION

Although initially engineered for cardiac surgery, surgical robotics has been dominated by urological interventions over the past two decades. The advantages of the robotic surgery platform have been well documented in over 10,000 peer reviewed publications, and include enhanced 3-D visualization, precision in movement, and accessibility to confined anatomical spaces. In fact, use of the robot has increased roughly 10 percent annually since the year 2000 despite significant concerns of cost sustainability.

One reason for the continued increase in numbers is the integration of the robot into abdominal, pelvic, thoracic and even head and neck surgery. A second reason is that after roughly twenty years of high volume use, urologists have expanded utilization of the robot outside the confines of oncology. Both upper and lower urinary tract reconstruction as well as benign disease have come into vogue for the practicing robotic surgeon. These procedures include simple prostatectomy for BPH, simple nephrectomy, cystectomy for the bladder cripple and urinary diversion. Additionally, the gamut of ureteral reconstruction including pyeloplasty, uretero-ureterostomy, ureteral re-implantation, psoas hitch and boari flap have been reported in multiple series. Finally, advanced ureteral reconstructive cases including revisional surgery after prior repair, ileal ureter, buccal mucosal grafting, appendiceal interposition and kidney auto-transplantation have all been attempted successfully at select centers of excellence.

This chapter will concentrate on the use of the robot for the above benign and reconstructive interventions and is intended as an overview for current practices in non-

oncologic robotic surgery. Particular focus will be paid to indications, technique with commentary from the author's surgical experience, and the most current literature.

ROBOTIC ASSISTED LAPAROSCOPIC SIMPLE NEPHRECTOMY

Simple nephrectomy refers to removal of the kidney itself, while leaving the adrenal gland, lymphatic tissue with the option to leave some or all of Gerota's fascia intact. Indications for the procedure include atrophy from recurrent infections or obstruction, non-function, nephrolithiasis, pain, trauma, familial or acquired cystic disease, and rarely, tuberculosis. Since the first simple nephrectomy performed by Gilmore in 1870, the procedure has undergone significant technical advancement with the popularization of laparoscopy, and then more recently, with the introduction of the robotic surgical platform [1]. In fact, the use of the robot in simple nephrectomy can be extremely beneficial as it is often more challenging than radical nephrectomy secondary to inflammatory processes that obliterate planes and mediate significant fibrosis [2].

Although several large series exist demonstrating the feasibility and utility of robotic assisted radical nephrectomy, there are no dedicated publications to robotic assisted simple nephrectomy. As these procedures are virtually the same, Table 1 details the most recent robotic radical nephrectomy series, some of which include simple nephrectomy within their cohorts.

Table 1. Recent series for robotic assisted radical nephrectomy

Preoperative Considerations, Equipment, and Set Up

Although this section deals with nephrectomy, the following technical points are common to all urological robotic cases, and are generalizable to the forthcoming sections in this chapter. At our institution we use both the Si and Xi robotic systems. All port placements are the same for both systems across all interventions. A single notable difference is the 8mm camera port for the Xi versus the 12mm camera port for the Si.

All patients are examined on the morning of surgery, their charts and imaging meticulously reviewed and proper laterality marked. Patients should be evaluated by a dedicated robotic anesthesia team who are well versed in the physiology and potential complications of robotic surgery. For all benign and reconstructive urologic robotic cases, 5000 units of sub-cutaneous heparin are administered alongside sequential compression devices and proper antibiotic coverage. All members of the team should be familiar and proactive in optimizing patient positioning and padding. Finally, the operating room should be large enough to accommodate the robot, surgical equipment, and the entire surgical team. Should an emergency conversion to open be indicated, quick access to open instrument trays and easy movement in and about the operating room can be lifesaving.

Surgical Technique and Outcomes

The technique for robotic nephrectomy mirrors the laparoscopic approach and has been well defined in the literature. The first robotic nephrectomy was actually performed for benign pathology and was described by Guillonnet in 2001 [3]. They reported on a non-functioning, hydronephrotic kidney secondary to UPJ obstruction that was successfully removed using an early robotic technology, the Zeus Robotic Surgical System (Computer Motion Goleta, CA). Thereafter in 2002, Horgan et al. reported on a cohort of 10 patients who had undergone robotic assisted laparoscopic donor nephrectomy [4]. The mean operative time (OT) and estimated blood loss (EBL) was 166 minutes and 68ml respectively. There were no intraoperative complications and no open conversions in this initial group. Interestingly, over the course of only ten cases the authors operative time considerably improved from 210 min for the first case to 140 min for the last, highlighting the ease at which the robotic platform was integrated into their surgical routine. Finally, Rogers et al. reported on a series of 42 patients, 7 of who underwent simple robotic nephrectomy and the remaining radical [5]. The mean operative console time was 158 min, mean EBL 223 mL and no intervention required open conversion. Taken together it is clear that robotic nephrectomy is feasible and reproducible.

Comments

There is significant variability in how robotic nephrectomies are approached in terms of access (transperitoneal vs retroperitoneal), port placement, patient positioning (flank, modified flank), and arm positioning (taped across the chest, anatomic position, Krause arm-rest, elevated over the head). Many surgeons draw from pure laparoscopic experience in defining their preferred approach. After 2500 robotic cases, we have optimized our technique specifically for a robotic approach and to make for an easily reproducible setup that minimizes complications and robotic arm interference. The configuration is detailed below and is used for all adrenal, kidney and upper ureteral procedures.

The patient is rolled into a near-full flank position with the iliac crest positioned just below the break of table. Rather than use individual pillows, blankets or bolsters to maintain the flank position, a single large roll, or “Hoagie Roll” as we term it, is placed posterior to the patient (Figure 1) and buttressed in position using two orthopedic hip positioners that are

clamped to the table. In this fashion, we are able to rapidly but gently place the patient in flank position and maintain the flank position without worrying about the patient slumping back after draping. The downside arm is supported with an axillary roll and secured to a perpendicular arm board in the usual fashion. We prefer to place the upside arm, however, in an anatomical position along the lateral aspect of the hip, taped loosely from posteriorly to prevent the arm from falling into the surgical field.

A 12 mm assistant port is placed peri-umbilically and the camera is placed through this port initially to facilitate further port placement. A straight line from the ribs at the mid-clavicular line down toward the lateral pubis is drawn out. Starting 2cm off the ribs, four 8mm ports are placed with one hand breadth between each along the previously marked line. (Figure 2) The robot is docked over the flank. This port configuration and robot docking methodology is the same for both Si and Xi robotic systems. Of note, the forth arm of the robot is intentionally left undocked for the initial portions of the case as it is not needed and allows for unhindered movement during bowel medialization. The 4th arm is docked after the ureter is identified and the kidney is ready for lateral retraction for access to the hilum.

Figure 1. Rather than use individual pillows, blankets or bolsters to maintain the flank position, a single large roll is placed posterior to the patient

Figure 2. Port placement for renal and upper urinary tract access. Note that the straight line makes access simple and reproducible.

There are several advantages to the above robotic set up for kidney surgery. Firstly, the lateralized placement of the camera significantly decreases obstruction from, and need to medialize, the bowel structures. The lateral camera position also facilitates an easier access line for the assistant. A zero degree lens with the camera port pulled back as much as possible enables a wide viewing angle to help mitigate what might be an altered view for some surgeons. Finally, this setup standardizes port placement in a way that reliably avoids robotic arm clashing and is easily reproducible by all members of the robotic team.

SIMPLE PROSTATECTOMY

Unlike simple nephrectomy, robotic assisted simple prostatectomy (RASP) is becoming well documented in the literature as the technique gains significant momentum in the urologic world. Interestingly, the current EUA and AUA guidelines still describe RASP as investigational secondary to lack of sufficient studies demonstrating value [6-7]. Yet, for glands that are not amenable to standard endoscopic management such as trans urethral resection, robotic simple prostatectomy is an excellent minimally invasive option that significantly enhances voiding parameters while preserving erectile and sexual function. Several approaches have been described and are outlined with peri-operative parameters in Table 2.

Table 2. Recent series of robotic simple prostatectomy with peri-operative parameters

Publication	Cohort size	Technique	IPSS pre-op	IPSS post-op	Pre-op Qmax (ML/s)	Post-op Qmax (ML/s)	Mean Operative time in minutes	Hospitalization Time in Days	Catheter time in Days
Pokorny 2015	67	Drop bladder, vertical cystotomy just above prostate-vesical junction, prostatic fossa is then retrigonized using a double-layer 3-0 V-Loc running suture.	25	3	7	23	97	4	3

Banapour 2014	16	Horizontal cystotomy proximal to the vesicoprostatic junction, no bladder neck reconstruction	22	7	Not Reported	Not Reported	228	1.3	8
Leslie 2014	25	Vertical incision in dome without dropping bladder. No bladder neck reconstruction	24	3.6	11.3	20	214	4	9
Matei 2012	35	Bladder dropped, horizontal cystotomy proximal to vesico-prostatic junction, Bladder trigonized by suturing posterior edge of bladder neck to posterior urethra	28	7	6.6	19	180	3.2	7.4

Surgical Technique and Outcomes

Patient positioning and port placement follows standard configuration for prostrate interventions with the patient in lithotomy and steep Trendelenburg. There are several technical aspects of the procedure that vary based on surgeon preference. These include a transvesicle or extravesicle approach, the decision to drop the bladder or not, and the performance of a bladder advancement anastomoses. Since the robotic procedure is still in its infancy without comparative studies, there is no consensus as to which techniques is best.

Single institution series for RASP are still relatively small with the largest experience capping out at 67 patients [8]. In that series, Pokorny et al retrospectively analyzed their experience with RASP and reported a median OT of 97 min (IQR 80 – 127), median EBL at 200 ml (IQR 115 – 360), median catheterization time of 3 d (IQR 2 – 4) and the median length of stay (LOS) of 4 d (IQR 3 – 5). More importantly at 6 months follow up the median IPSS score was 3 (IQR 0 – 8), with a median post void residual (PVR) of 0 ml (IQR 0–36). The postoperative complication rate was 30%, including three cases (4.5%) with grade 3b complications (major bleeding requiring cystoscopy and coagulation). A multi-institutional consortium reported similar results from 487 RASP procedures utilizing various approaches with a roughly 16% complication rate of which only 12 were above Clavein 2 [9]. OT was reported at 154.5min (100 – 180), EBL of 200cc (100 – 400), and LOS was 2 days (1 – 4).

Comments

At our institution, we have stopped mimicking the open approaches such as the traditional retropubic or suprapubic techniques. Instead, we use a retzius sparing, posterior transvesical approach for simple prostatectomy. The bladder is left in-situ and not dropped. Instead, a generous, vertical cystotomy is made at the midline from the dome to the floor of the bladder. Keith needles are passed through the lateral abdominal walls, bilaterally, to provide static retraction at the bladder incision. The adenoma is accessed and resected through this posterior cystotomy incision. Using a combination of monopolar cautery and blunt dissection, the adenoma plane is followed, taking care to avoid the capsular plane. After the adenoma is resected, the bladder mucosa is circumferentially advanced and anastomosed to the urethra using a running 12 inch 3 - 0 VLOC barbed suture. Prior to closing the bladder, 10 cc of Floseal (Baxter) is then injected into the prostatic fossa after the anastomosis.

The main advantage to our technique is twofold. The 360-degree bladder neck anastomosis to the prostatic urethra provides complete urothelium to urothelium approximation, resulting in a reliable resolution of postoperative hematuria, obviating the need for continuous bladder irrigation and allowing for an 18 French 2-way catheter postoperatively. Secondly, since the bladder is not dropped, the prostatic dissection is extraperitoneal.

Simple Cystectomy

Simple cystectomy is a rare procedure in current urological practice with published data limited to small, single center, case series. Indications for simple cystectomy are primarily for

severe refractory voiding dysfunction, recurrent inflammation or infection, and life-threatening hematuria, with some reports of other more esoteric indications published as single case reports. A recent analysis of all cystectomies performed in the US from 2005-2014 found that out of roughly 5000 cystectomies, only 8% were performed for benign indications [10]. The rarity of this procedure is likely multifactorial, however, the known morbidity of cystectomy and subsequent urinary diversion is, in all likelihood, the major deterrent in performing this procedure.

For those individuals whose risk of intervention is outweighed by the morbidity of their condition, robotic cystectomy is feasible, and is supported by numerous series from the oncological literature. The approach to robotic simple cystectomy and urinary diversion is similar to radical cystectomy with the exception of sparing all Wollfian and Mullerian structures that would normally be excised in the radical procedure. Lymphadenectomy is also usually skipped and not needed unless intraoperative findings warrant it. There are no published series of robotic simple cystectomy with intracorporeal diversion.

Surgical Technique and Outcomes

Port placement and positioning follows standard configuration for robotic pelvic interventions, and for most, the procedure begins with ureteral identification and transection. Thereafter, several techniques have been described for bladder mobilization, reservoir creation, and ureteral implantation. In 2014 Abreu et al. reported on a large cohort of completely robotic cystectomy and urinary diversion with 57 patients undergoing intracorporeal ilial conduit and 46 with intracorporeal orthotopic neobladder [11]. The authors report a mean OR time of 420 min, EBL of 200 mL, average LOS of 7 days, and a 30-day Clavien 1-2 and 3-5 complication rate of 42% and 17% respectively. The study demonstrated, among other things, the feasibility and reproducibility of both intracorporeal ileal conduit and neobladder procedures. Intracorporeal continent urinary diversion has also been described. Desai et al. reported on a cohort of 10 patients, who underwent intracorporeal Indiana pouch creation in conjunction with cystectomy [12]. They reported similar operative time to ileal conduit creation, no intraoperative complications, and no transfusion requirements. In both the above studies, malignancy was the indication for the procedures and OT and EBL may be skewed secondary to extensive node dissections that may be skipped in the setting benign indications.

In 2017 Aisen et al. explored patient characteristics and complications of simple cystectomy [13]. Drawing on patients from the National Surgical Quality Improvement Program, they reported no significant difference in complication rates between radical and simple cystectomy (60.4% vs. 57.7%, $p = 0.3$). They did however, identify a significant increase in rate of infection in the benign cohort (31.1% vs 25.1%, $p = 0.009$). This could be secondary to the fact the recurrent cystitis is a common indication for simple cystectomy.

RECONSTRUCTION

Upper urinary tract reconstruction is a complicated field associated with considerable morbidity, and has classically been managed in an open fashion because of significant fibrosis and poor surgical planes [14-15]. Use of the robot in this area of urology has only recently become popular with experienced robotic surgeons. Literature pertaining to robotic upper tract reconstruction is sparse with few publications reporting on small cohorts. Despite this, the topic is of considerable importance as management of ureteral defects can be exceptionally frustrating to both patient and clinician.

Ureteral defects are most often caused by trauma/surgical injury, urolithiasis, radiation, malignancy and even infection such as tuberculosis [16-19]. Ureteral reflux, although not technically a defect in the ureter itself, is also a common cause for reconstructive surgical intervention. Management of these pathologies, includes pyeloplasty, uretero-ureterostomy (UU), ureteral reimplant (UR) with or without psoas hitch, boari flap, and ileal ureter- all of which have been described robotically. The choice of reconstructive technique hinges on several components such as length of defect and the segment of ureter involved. Additionally, the use of appendix and buccal mucosa for ureteral reconstruction has recently been reported. Each of these surgical techniques will be considered in this section.

Prior to this discussion, it is worthy to mention Indocyanine green (ICG) and its important adjunctive tool in the field of robotic ureteral reconstruction. ICG is a cyanine dye, that when injected intravenously, can be visualized as bright green under near-infrared fluorescence (NIRF), a visual setting that can be turned on and off on the robotic platform. The dye is an ideal intraoperative contrast agent because it has a high signal-to-noise ratio, and an excellent safety profile [20]. Within urologic surgery, the dye was initially proposed for to assist in margin identification during partial nephrectomy. It gained popularity when it was used *intravenously* to aid in selective arterial clamping in partial nephrectomy [21]. In ureteral reconstruction, intravenous ICG can be used to define the vascular supply of the ureter prior to anastomoses or re-implantation with the hope of avoiding anastomotic breakdown or repair failure [22]. It can also be used to assess the vascular supply to an omental flap for interposition [22]. Even more recently, *intraureteral* ICG, an off-label use of the dye, has demonstrated itself to be an invaluable tool in identifying the ureter and site of injury in hostile fibrotic environments [23]. The dye comes in 25mg vials that is mixed in 10cc of water and can be injected antegrade down a nephrostomy tube or retrograde via a ureteral catheter prior to robotic intervention. The ureter then fluoresces within the dense fibrotic tissue aiding in ureteral identification. In this setting, the dye can also identify strictures and poorly perfused ureteral tissue thus helping to identify areas where intervention is needed. In 2013, Lee et al reported on their use of intraureteral ICG on a series of 7 UU repairs [23]. ICG was injected both retrograde and antegrade to both define the ureter and pinpoint the ureteral defect. In 2015, the same authors reported their use of the dye in a cohort of 25 patients undergoing robotic ureteral reconstruction [24]. The results confirmed the feasibility, utility and safety of intraureteral ICG in cases of ureteral reconstruction.

At our institution, ICG and NIRF is used in variable ways depending on the clinical scenario. We outline three different ways that NIRF can be used in complex ureteral reconstructive cases. ICG is a distinctive benefit of the robotic platform since the NIRF setting can be easily toggled on and off at the push of a button. In practice, intraureteral ICG

can be used when faced with severe retroperitoneal fibrosis where significant amount of time can be wasted in identifying the ureter and there may be a real concern for a vascular injury. 5cc of ICG can be placed into the ureter via a 5 French retrocatheter or down a percutaneous nephrostomy tube. This use of ICG is off label and should be discussed with the patient. However, once the labeled urine is spilled, the ICG stains the entire operative field and renders an intravenous application useless. Alternatively, an intravenous approach can be used if the surgeon hasn't applied ICG into the ureter. Once the ureter is identified, 2-3 cc of intravenous ICG can be given to help delineate vascular perfusion of the ureter, bladder and even omentum. In cases where there is a concern of ureteral ischemia (i.e., radiated ureter, pyeloplasty failure, reoperation on a ureter) an intravenous application of ICG can be very helpful in guiding your dissection and deciding where to excise and reanastomose. Intravenous ICG washes out, so intravenous ICG doses can be repeated every 20 minutes to reassess tissue perfusion and vascular integrity of your repair. Lastly, NIRF mode can be used in conjunction with conventional scopes with white light, without the use of ICG. For example, a ureteroscope in the ureter can be used to identify the specific location of the ureteral stricture. With the endoscopic white light turned on, the NIRF mode can be turned on and the white light will be seen as a green fluorescent signal. When using NIRF in this fashion, you can reserve use of the ICG for later in the case to help delineate perfusion information. Make sure the endoscopic light source is turned off promptly to avoid inadvertent thermal injury.

PYELOPLASTY

Robotic assisted laparoscopic pyeloplasty for uretero-pelvic junction obstruction (UPJO) represents one of the most common robotic non-oncological procedures performed by urologists. Although generally associated with the pediatric population, adult UPJO requiring pyeloplasty has a prevalence of roughly 1/1500 adults, and can be secondary to nephrolithiasis, ureteral manipulation, crossing vessels, outlet obstruction, and even idiopathic causes [25].

Table 3. Recent series for robot-assisted laparoscopic pyeloplasty in adults

Study	Cases	Approach	Operative Time minutes	Conversion rate, %	Complication rate, %	Hospitalization time in days	Success rate as a %
Sivaraman et al.	168	Trans	134.9	0	6.6	1.5	97.6
Minnillo et al.	155	Trans	198.5	0	11	1.95	96
Olsen et al.	67	Retro	146	1.5	17.9	2 †	94
Mufarrij et al.	140	Trans	217	0	10	2.1	95.7
Schwentner et al.	92	Trans	108	0	Not Reported	4.6	96.7
Etafy et al.	61	Trans	335	0	11.4	2	81
Gupta et al.	86	Trans	121	2.3	9.3	2.5	97
Cestari et al.	55	Retro and Trans	138.5	0	1.8	3.6	96

The first robotic pyeloplasty series was reported in 2002 by Gettman et al. [26], and since then, its use has steadily increased in popularity representing less than 10% of pyeloplasties in 2006, to 33% in 2007, to more than 80% in 2008 [27-28]. Since then, multiple large series have been reported in the adult population and are summarized with peri-operative parameters in Table 3. One of the largest reported series of 169 patients is reported by Sivaraman et al., who pooled data from three US institutions and confirmed that robotic Pyeloplasty represents a feasible, efficacious, and reproducible intervention for UPJO with high success rates and minimal complications [29].

Technical Considerations

Surgical Approach

Several surgical approaches, including retro-colic, trans-mesocolic and retroperitoneal methodologies have all been reported for robotic pyeloplasty [30]. Shadpour et al. was the first to compare minimally invasive trans-mesocolic pyeloplasty with the standard retrocolic approach in a prospective randomized fashion [31]. They analyzed 64 patients randomized between retrocolic and trans-mesocolic groups with each cohort consisting of 32 patients matched for gender, age, BMI and renal function. Results showcased a marked decrease in time from port placement to UPJ transection translating into a roughly 23% decrease in overall operative time. Although success rates were similar at 97%, length of stay in the trans-mesocolic group was significantly shorter (mean: 2.9 vs 3.6 $p < 0.001$). Gupta et al. reported the outcomes of 24 trans-mesocolic robotic pyeloplasties with mean operative times reported at 125 min, and a 43 minute anastomoses time [32]. LOS was an average of 2.5 days, and a 100% success rate as defined by radiographic evidence of obstruction.

More recently, accessing the UPJ from a retroperitoneal approach has become popular following data reported from robotic retroperitoneal partial nephrectomy series. [33]. The advantages of retroperitoneal access include rapid access to the renal pelvis, elimination of urine spillage into the abdomen, and prevention of injury to the intra-peritoneal structures. Yet, concerns surrounding anatomic orientation, and restricted work space represent universally recognized limitations. Several retroperitoneal series for both adult and pediatric populations have been reported. A recent meta-analysis addressing retroperitoneal versus trans-mesocolic approaches did not demonstrate significant differences in success rates, complications or length of stay [34]. Significant differences were, however, reported favoring the trans-mesocolic approach, in operative time (mean reduction 44.9 min) and risk of conversion to open (RR 0.4). The above meta-analysis included a single prospective randomized trial.

Surgical Technique

Aside from the Anderson-Hynes dismembered pyeloplasty, several other robotic techniques have been reported, including the Fenger, Y-V plasty, spiral flap, and several variations of each [35-38]. The Fenger reduces operative time with short stenotic segments by simply making a longitudinal incision followed by a transverse suture line. The Y-V plasty is ideal for ureters with high insertion into the UPJ, and the spiral can reduce the size of a dilated renal pelvis. Despite these reports, however, there is no level one evidence suggesting

superiority of one technique over another for any given population. A final alternate technique is the vascular hitch procedure which entails transposing aberrant lower pole renal vasculature, and is a method for addressing UPJO without re-anastomosis of the upper urinary tract [39]. Various studies have demonstrated efficacy in carefully selected patients, and the procedure should be utilized on a case by case basis until stronger evidence of its durability is published. [39-40].

Comments

Refining the technique of pyeloplasty remains an extremely active area of research. Each case is unique and the repair considerations need to be adjusted on a case by case basis. Understanding and addressing the cause and extent of the obstruction remains the greatest challenge for the pyeloplasty surgeon. Minimizing direct handling of the ureter, avoiding over dissection of the ureter and consideration of the vascular blood supply are all challenging technical aspects of robotic pyeloplasty. In addition, a number of methods for starting the ureteropelvic anastomosis prior to completing transection have recently been proposed with comparable results to the standard technique [41]. Utmost care must be taken when anastomosing the apex of spatulation and typically we take two throws in the corner for extra support. At our institution, we utilize a 5-0 monocryl suture (Ethicon) on a tapered TF needle, cut to 6 inches for the anastomosis. We typically will perform a running anastomosis on one

side, followed by deploying a double J stent placement and finally, running another 5-0 monocryl suture on the remaining side. Reduction of the renal pelvis should be considered in cases where the renal pelvis is excessively capacious.

URETEROURETEROSTOMY (UU)

UU technically represents one of the more straightforward ureteral reconstructive procedures with an excision and primary anastomoses of the ureteral defect. In practice, UU can be extremely challenging due to mechanism of injury and periureteral tissue quality and fibrosis. The technique presumes that no tissue interposition is required to bridge the gap in the ureter generated by the defect, and is generally utilized in the mid to upper sections of the ureter. Work by De Cicco et al. in a review of all published UU series from 1990-2006 established the feasibility of minimally invasive UU [42]. Since that time, only scant literature has surfaced on robotic UU.

Surgical Technique and Outcomes

Port placement and positioning for UU follows configuration for kidney work with the patient in flank/modified flank and the table flexed. In 2010, Hemal et al. reported on seven proximal robotic UU repairs for benign strictures [43]. Cases began with medializing the colon and varying degrees of ureterolysis depending on the particular pathology. Mean OR

time was reported at 110 minutes (range 85 – 140), with an average EBL of 50 cc (range < 50 – 75), and a mean LOS of 3 days (range 2 – 6). There were no reported complications and at 28 months all patients were symptom free. In 2013 Lee et al. reported on a series of 13 UU repairs spanning from proximal to distal defects [44]. Port placement and patient configuration was flank for proximal and mid ureteral inventions, and lithotomy with pelvic ports for distal repairs. Additionally, downward nephropexy was performed concurrently in all proximal/mid ureteral repairs to ensure tension free and watertight anastomoses. They reported mean operative room time of 190 minutes (range 104 – 354), EBL of 181cc (range 50 – 400), and mean LOS of 1.4 days (range 1 – 5). Although there was one intraoperative complication involving injury to the gallbladder secondary to trocar placement, there were no postoperative complications and at 10 months all patient except one were symptom free. Finally, in 2014 Fifer et al. reported on 5 robotic UU repairs within a larger series of 55 patients who underwent robotic repair of ureteral defects from below the UPJ to the ureterovesicle junction [45]. Although only composite results are tabulated without breakdown of perioperative parameters by type of repair, none of the 5 patients who underwent robotic UU had any form of complication and at a mean follow up of 6 months.

Comments

Traditionally, definitive surgical management for distal ureteral defects has been ureteroneocystotomy with surgeons shying away from performing UU in distal injuries. The support for this trend originates from reports touting that distal UU is accompanied by a higher failure rate secondary to disruption of the delicate plexiform vessels that supply the distal ureter and the difficulty of operating in the deep pelvis [46-47]. Yet avoiding re-implant comes with significant benefits including preservation of bladder integrity and the natural anti-reflux mechanism. In a retrospective report of nine open UU repairs, Paick et al. demonstrated the feasibility and durability of UU in the distal ureter for select patients with non-complex, short, distal ureteral injuries [48]. Our experience with robotic distal UU underscores these findings with 7 patients undergoing successful distal UU repair without intra/postoperative complication and 100% success rate to date [49]. In general, we perform distal UU when the ureteral stricture is short (< 2cm), when the stricture location is > 2 cm from the ureteral insertion and if we can attain a tension free watertight anastomoses. When performing UU in the distal ureter, it is important to try and preserve the distal ureteral blood supply coming from the internal iliac artery whenever feasible. We utilize a 5-0 monocryl suture (Ethicon) on a tapered TF needle, cut to 6 inches for the anastomosis. Once on half of the anastomosis is completed, a double J stent is left across the repair before running another 5-0 monocryl suture on the remaining side. At the end of the case, we cystoscopically confirm that the distal stent is properly located in the bladder.

ILEAL URETER (IU)

Interposition of bowel into the upper urinary tract is indicated in the repair of complex and lengthy ureteral strictures and was initially described by Shoemaker in 1909. Although

significant morbidity accompanies it, modern series have established the efficacy of the IU with regards to preservation of renal function [50-55]. The surgical technique has been performed robotically, in limited series, with the most recent reports being summarized in Table 4.

Table 4. Summary of most recent series for minimally invasive ileal interposition

Study (Year)	No. of patients	Ileo-vesical anastomosis	Median operative time minutes (range)	Median EBL (mL) (range)	Perioperative complications (Clavien grade)	Median hospital stay (days) (range)
Wagner et al. (2008)	1	Robotic	720	Minimal	None	5
Brandao et al. (2014)	1	Robotic	420	50	None	4
Sim et al. (2014)	5 ^a	Laparoscopic	250 (150 - 320)	100 (50 - 200)	Migrated stent (3b), Fever (2)	8 (6 - 10)
Chopra et al. (2016)	3	Robotic	450 (420 - 540)	100 (50 - 200)	Small bowel necrosis (4a)	9 (2 - 12)
Urbig et al. (2017)	7	Robotic	328 (261 - 394)	100 (50 - 200)	Anastomotic urine leak (3b)	25 (6 - 79)

^a four cases were laparoscopic, one was robotic.

Surgical Technique and Outcomes

The surgical technique for ileal ureter closely follows that for the open procedure and has been previously described [56]. Robotically, port placement and positioning are challenging to work concomitantly on the upper and lower tract with bowel interposition and proper patient position and port configuration are critical for success. Brandao et al. reported their technique for robotic ileal urter in 2014 on a single patient utilizing a three-arm approach [57]. Patient positioning started in modified flank, transitioned to lithotomy and was then repositioned back into modified flank for the final anastomoses. OT was reported at 420 minutes, EBL was 50cc, foley removal after cystogram on post op day 12, and at two years follow up the patient had stable renal function. A recent report of robotic ileal ureters from Chopra et al. in 2016 describes a 4 arm approach where the operation begins in flank position for bowel mobilization, transitions to lithotomy for lower tract/bladder access and bowel harvesting, and finally repositions back into flank for the final anastomoses of the bowel to the upper tract [58]. They reported their outcomes on a cohort of three with median OT at 450 minutes (range 420 - 540). EBL of 150cc (range 50 - 200). Two out of the three reported good outcomes without the need for further surgical intervention while one patient developed volvulus and subsequently required a takedown of the ileal ureter.

Comments

Interposition of bowel into the urinary tract stands as a last resort in cases where there is an extensive ureteral defect. We typically place the patient in modified flank position with a 4-arm approach and repositioning is not usually necessary. The ports are placed linearly along

the mid-clavicular line and the most caudad port is used as the daVinci stapler port. We use the robotic 45mm blue load staples to perform the ileal transection and bowel re-anastomosis. It is important to remember that on the left side, the entire ileal segment needs to be delivered under the IMA and sigmoid colon mesentery. Although a single dock approach is feasible on the Si platform, the Xi platform has made this procedure much easier with less external collisions due to its lower profile and less bulky arm design.

BOARI FLAP

For distal ureteral strictures not amenable to re-implant (4 - 5cm) or re-implant with psoas hitch (6 - 10cm), a boari flap is an acceptable alternative with acceptable success rates well documented in the literature [59]. As with other open procedures, the transition to minimally invasive approaches started with laparoscopy [60] and transitioned to robotics more recently. Table 5 documents the few known series of robotic ureteral re-implants with Boari Flap.

Table 5. Summary of the current literature on robot-assisted ureteral reimplantation with Boari flap

Report	Diagnosis	Number of renal units	Boari flap renal units	Other procedures	Operative time for Boari flap Minutes	Complications in Boari flap cases
Schimpf and Wagner 2009	Benign strictures, lymphoma, diverticulum, urothelial carcinoma	11	2	9 reimplantations (3 cases with psoas hitch)	150, 188 (robotic time)	External iliac vein injury (robotic repair) x 1 case Ileus x 1 case
Kozinn et al. 2012	Benign strictures	10	2	8 reimplantations (4 cases with psoas hitch)	Not reported	Not reported
Musch et al. 2013	Benign strictures, megaureter, urothelial carcinoma	18 (2 bilateral cases)	2	14 reimplantations (4 cases with psoas hitch), 1 end-to-end anastomosis, 1 ureterolysis and omentum wrap	230 - 320	Prolonged anastomotic leakage x1, bladder wall insufficiency x1, urinary tract infection x 2
Stolzenburg et al. 2016	Benign and malignant ureteral stricture, iatrogenic injury	11	11	Not Reported	166 (115 - 240)	Prolonged anastomotic leakage x 1

Surgical Technique

Surgical technique for robotic ureteral re-implant with boari flap mirrors the open procedure which has been well described previously [59]. In 2014 Do et al. reported on their series of 8 patients who underwent robotic ureteral re-implant with Boari flap [61]. Patient

positioning and trocar placement was similar to standard pelvic interventions with the patient in lithotomy and steep Trendelenburg. The bladder flap was created with a 2:1 length to width ratio and hitched to the psoas muscle prior to ureteral tunneled re-implantation as described by Leadbeter and Politano [62]. Results demonstrated average OT of 172 minutes [115 - 240], EBL of 161 [50 - 250] catheterization time of 7 days [6-12], and 12 month follow up with no significant complications associated with the procedure. In 2016 Stolzenberg et al reported on their series of 11 patients utilizing the same technique for robotic re-implant and Boari flap [63]. They reported an operative time of 167 min (Range: 115 - 240) EBL of 155cc [50 - 250], catheterization time of 6.7 days [6-12], and recurrence free follow up of 15 months [6-24].

Comments

We recommend performing a cystogram or videourodynamics during the surgical planning phase to ensure patient has a minimum of 400 cc bladder capacity. The patients should be counseled that their bladder capacity may be decreased and may impact their postop urinary symptoms. A patient with significant bladder instability or a patient with prior pelvic radiation is not a good candidate for a Boari flap. It is important to make sure a wide based flap is taken to ensure that the apex of the flap has adequate blood supply. We recommend using intravenous ICG and NIRF to assess real-time blood supply of the bladder and flap prior to committing with ureteral anastomosis.

URETERAL RE-IMPLANT

The distal third of the ureter is one of the most common sites requiring reconstructive intervention. Aside from being susceptible to general pathology that effects the ureters, the distal ureter courses in close proximity to the female reproductive organs, thus at increased risk for injury during gynecologic surgery. The rate of ureteral injury in gynecologic surgery ranges from 0.03% to 1.3% with laparoscopic and robotic procedures being greater risk factors for ureteral injury [64]. In reality, however, the rate of ureteral injury in pelvic surgery is commensurate with experience, and at some hospitals, can be significantly higher. Short defects arising from non-malignant disease is usually managed by ureteral re-implant, and is a common reconstructive urological intervention. Majority of the literature pertaining to robotic ureteral re-implantation emanates from the pediatric population where it is used to definitively treat vesico-ureteral reflux. A recent multi-institutional study published in 2017 by Boysen et al reported on a cohort of 363 ureters that were robotically re-implanted in the pediatric population [65]. They reported a roughly 90% success rate defined radiographically with only 25 overall complications majority of which were clavien 1-2. In the adult population, a handful of series report on their experience with robotic ureteral re-implant for benign disease and they are presented in Table 6.

Table 6. Recent series for robotic assisted ureteral re-implant

Reference	Patients	Procedure	Operative time (minutes)	Estimated blood loss (mL)	Length of stay (days)	Complications	Follow-up (months)	Outcomes
Yang et al. 2011	2	1 Reimplant with Boari flap, 1 with psoas hitch	Not Reported	75	5	None	2 years 1 patient	One patient with no hydronephrosis; 1 lost to follow-up
Kozinn et al. 2012	9	6 Reimplants 3 with psoas hitch 1 Boari flap	307	30.6	2.4	None	Up to 24 months	No hydronephrosis
Isac et al. 2013	25	11 Reimplants 4 with psoas hitch, 10 with with Boari flap	279	100	3	2/25 (7.9%): required reoperation	11.6	Two failures requiring further surgical intervention
Musch et al. 2013	9	5 Reimplants 2 with psoas hitch 2 with Boari Flap	271 (153 - 460)	Not Reported	12 (5 - 35)	5/9 (55.5%): 2 Clavien 3b 1 Clavien 4a	11 (4 - 18.2)	1 patient with persistent hydronephrosis
Wason et al. 2015	13	6 primary UNC, 8 UNC with psoas hitch	282 (174 - 418)	123 (20 - 600)	2.5 (1 - 8)	3/13 (23%): 2 Clavien 3b	9.8 (2.3 - 20)	No hydronephrosis

Surgical Technique and Outcomes

Patil et al. were the first to report robotic experience with benign ureteral disease and ureteral reimplantation in 12 patients from a multinational institutional dataset [66]. Patient positioning and port placement followed standard protocol for pelvic interventions with the patient in lithotomy and steep Trendelenburg. The procedures began with mobilization of the colon followed by ureteral identification and ureterolysis to varying degrees. In all cases a stent was left across the anastomoses. Significant findings included a decrease in blood loss and hospital stay in comparison to the open technique on top no reported complications, and no evidence of recurrence at 15 months follow up. Isac et al. retrospectively reviewed and compared their series of 25 patients who underwent robotic re-implant with 41 patients who had open re-implants [67]. Significant results demonstrated lower EBL (100cc VS 150cc $p < 0.05$) shorter hospital stays (median, 3 versus 5 days $p < 0.05$), less narcotic use (104.6mg versus 290mg Morphine $p < 0.05$) and no significant difference in the rate of re-operation (2/25 (7.6%) VS 4/41 (9.7%) $p < 0.05$). The robotic approach did, however, log longer OT (Avg 200 VS 279 $p < 0.05$). More recently in 2015 Wason et al. reported on their series of 13 patients involving 14 re-implants, one of the largest single institution series for ureteral re-implantation for benign pathology [68]. Mean overall OT was 282 min (range, 174 – 418), and EBL was a mean of 123cc (range, 20 – 600). Patients spent an average of 2.5 in

the hospital (median, 2; range, 1 – 8), and mean follow-up was roughly 10 months (range, 2.3 – 20). All patients were reported asymptomatic at the time of publication. A standard Bricker refluxing anastomoses was utilized in this series, and although non refluxing re-implants have been described depending on surgical indication, use of a refluxing anastomoses more avidly prevents re-stenosis than does a non-refluxing.

Comments

Except for intervention to prevent refluxing ureter pathology, most indications allow for a non-tunneled, refluxing ureteroneocystostomy. For the anastomosis, a running 4-0 or 5-0 Monocryl (Ethicon, Sommerville, NJ) suture on a TF or RB-1 needle is recommended. Except for the most distal ureteral injuries or obstructions, most ureteral reimplantations, including most resulting from gynecologic complications, will require a psoas hitch to produce a tensionless anastomosis. It is important to completely free the bladder from the space of Rezius to enable maximal bladder mobility. Dividing the contralateral superior vesical artery can offer a modest improvement in bladder mobility. It is important to clean off the psoas fascia before performing the hitch stitch to avoid inadvertent entrapment of the genitofemoral nerve and ensuring that psoas tendon is well identified. In some cases, a psoas tendon is absent and psoas fascia will have to suffice. We recommend that at least 3 point of suture fixation are taken to secure the hitch. Since tying tensioned sutures can be challenging, we prefer using an absorbable Laproclip (Medtronic) to perform a sliding clip maneuver on an 0 VLOC suture with a GS-21 needle as the hitch stitch. The sliding clip technique has been popularized for renorrhaphy during partial nephrectomy and enables a uni-directional ratcheting mechanism so that the hitch can be gradually tensioned without the need to tie a knot.

BUCCAL MUCOSA ONLAY GRAFTS

Ureteral defects of the mid to upper ureter where a tension free anastomoses is unattainable even after downward nephropexy are a unique challenge to the reconstructive urologist. With classic treatment options warranting bowel interposition or nephrectomy, it was clear that a better option was needed to bridge gaps in the ureter that fell just short of successful UU. With established animal models in baboons touting encouraging results, in 1999 Naude reported the first buccal graft ureteroplasties on a cohort of 6 patients [69]. Performed in the open technique, the author reported no complications and patent ureters on retrograde pyelograms at 3 months post operatively. Since his initial report, several small series have been reported in the open surgical literature [70-71].

Surgical Technique and Outcomes

The first report of robotic buccal mucosa ureteroplasty was in a cohort of 4 patients by Zhou et al. in 2015 [72]. Patient positioning was flank and similar to robotic kidney

interventions with the table flexed at the hip. Mean stricture length was 3cm with two patients undergoing posterior onlay, one patients undergoing anterior onlay, and one patient with augmented anterior onlay anastomoses. Oral mucosa was harvested by an otolaryngologist at a length that was pre-defined based on the length of the stricture after ureterolysis and the borders of pathology clearly defined. They reported no intraoperative complications, average EBL of 75cc, average operative time at 298 min, and no evidence of reoccurrence at 15 months. More recently, Lee et al. presented a cohort of 12 patients that underwent buccal ureteroplasty for a mean stricture length of 3cm [73]. With similar patient positioning they reported on two methodologies of ureteral reconstruction: longitudinal incision of the anterior stricture with subsequent buccal onlay graft, and complete stricture excision with posterior primary repair and anterior augmented buccal graft anastomosis. In the case of total stricture excision, the procedure involved downward nephropexy to shorten the overall ureteral defect. The Oral mucosa was harvested by a reconstructive urologist at a predefined length based on the identified ureteral defect. After the reconstruction, all patients received an omental wrap to protect the anastomoses and nurture the graft. Results included no reported intraoperative complications, mean operative time of 217min, average EBL of 100cc, and at a mean follow up of 13 months 10/12 patients were symptom free.

The largest buccal graft series to date was recently published in late 2017 by Zhao et al. from a multi institutional data set [74]. Incorporating 19 patients, the augmented anastomotic repair was utilized in ~ 20% of patients while the remaining patients underwent an anastomotic repair. The median stricture length was 4.0cm (2.0 - 8.0), operative time was 200min (136 - 397), estimated blood loss was 95cc (25 - 420), and length of stay was 2 d (1 - 15). No intraoperative complications were reported and at median follow-up of 26 months, success rates were reported at ~ 90%. Of note, more than 50% of these interventions were redo procedures after failed non buccal repairs.

Comments

The use of buccal mucosa to reconstruction of the upper tract ureter has revolutionized the management of an exquisitely difficult to treat patient population. Furthermore, the application of this technology to the minimally invasive robotic platform has made this treatment option more accessible to patients given all the technical advantages provided by the robot not available to the few skilled reconstructive urologists who perform these procedures open. One unique aspect of this operation is that since dissection is only localized to the stricture site, failure of this procedure doesn't preclude the more traditional options such as ileal ureter or Boari flap. In addition, since it is meant to minimize disruption of blood supply, it is well suited to revision of a pyeloplasty, unlike a spiral flap. In contrast, blood supply is brought in via omental flap. There are several intrinsic characteristics of BM that make it well suited for incorporation into the urinary system. Firstly, the oral cavity is a hairless, aqueous environment as is the urinary tract. Secondly, exposure of BM to urine does not mediate an inflammatory response which would put the graft in danger for rejection as does keratinized epithelial grafts [75]. Finally, the thick epithelium, thin lamina propria, and matured vascular plexus of BM allow the graft to take exceedingly well [76].

At our institution, intravenous or intraureteral ICG and NIRF is routinely used for these types of cases due the significant amount of peritureteral fibrosis and variable blood supply to

the area of pathology. Using these adjuncts has helped to cut down on excessive ureteral dissection and OR time. Additionally it is helpful to define vascular supply to the ureteral defect which affects the type of repair utilized. If the entire defect has no blood supply, the segment of ureter is excised, a posterior ureteral plate is approximated, and the graft is then onlayed to create an augmented anastomosis. Alternatively, if the strictured segment has adequate blood supply and there is a usable lumen, the anterior wall of the stricture can be sharply incised longitudinally and repaired with an anterior onlay graft.

Suturing your graft is easiest if the ureterotomy is made antero-medially and not posteriorly. In all of our cases, we utilize omentum to deliver blood supply to our graft, therefore the anastomosis is easiest antero-medially. In the rare case that omentum is not available, the ureter may need to be opened posteriorly to gain blood supply directly from the psoas muscle. In these cases, the BMG should be sutured directly into the psoas muscle bed making ureteral anastomosis much more technically challenging. Regarding buccal graft harvesting, we always advise measuring your ureteral defect intracorporeally prior to harvesting the graft. To avoid aneurismal dilation of the BMG, we advise fitting the graft to size and not oversizing it. We use 5-0 moncryl suture on a TF needle, cut to six inches for each half of the anastomosis. 6 French double J stent is usually placed halfway through the completion of the ureteral repair.

APPENDICEAL INTERPOSITION

For ureteral defects that are too long for buccal grafts and would otherwise be amenable to ileal ureter, use of the appendix interposed in the urinary tract stands as a new and attractive option. Originally described in 1912 [77]. Only few reports of this technique have been published and almost all describe use of the appendix as an onlay graft similar to buccal mucosa [78-79].

A recent report from Kavoussi and colleagues in 2015 described 6 laparoscopic appenaceal onlay reconstructions for ureteral stricture disease [80]. They reported feasibility with only a single patient requiring subsequent nephroureterectomy for reasons unrelated to the graft.

Surgical Technique and Outcomes

Although we are aware of several institutions that have performed robotic appendiceal interposition, only a single robotic appendiceal interposition publication exists out of the university of Alabama at Birmingham [81]. In this case report, they describe a patient with a 5cm right sided stricture that was successfully treated with a robotic appendiceal interposition. Operative time was roughly 6 hours with 100cc of blood loss, LOS of 2 days, and at 10 months there was full resolution to hydronephrosis and no clinical symptoms of obstruction.

The full surgical procedure is fully described in the publication. Briefly, a mesenteric window is created in the mesoappendix, with subsequent ligation of the appendix off the cecum. Both the proximal (opposite the cecal end) and distal appendiceal ends were

spatulated on the antimesenteric side and residual fecal matter is removed. The proximal and distal ends of the ureter are then spatulated on the contralateral side of the appendiceal spatulation and anastomosed. After stent placement, the cecum and right colon are tacked to the abdominal sidewall to relieve possible vascular on the repair.

Comments

The most important advice is to ask your patient preoperatively in the office if the patient has ever had an appendectomy. For complex ureteral reconstructive cases, it is imperative that the surgeon goes into surgery with a well laid out plan. Usually, the appendix is best suited for right sided strictures, as tunneling the appendix under the sigmoid mesentery to reach the left ureter is unlikely. As long as the mesoappendix is well preserved, the appendix can serve as either a tubular ureteral replacement or as an onlay. For longer strictures that require more tissue than buccal mucosa can provide, use of the appendix has several benefits over the standard ileal ureter. Firstly, the caliber of the appendix more closely approximates that of the ureter making the anastomoses less cumbersome. Secondly, the small diameter limits the contact urine has with the intestinal tract and thus protects against metabolic imbalances. Finally, it does not require a bowel anastomoses which stands as a well known source of post operative complications. It is worthy to mention as well that appendiceal interposition does not preclude the patient from future ileal ureter should it fail.

CONCLUSION

Robotic urologic surgery is an ever progressing field with our ability to push boundaries aided by consistently advancing technologies Robotic laparoendoscopic single-site technique (R-LESS), is a technology on the horizon that was first explored in 2005 with the idea of a single port in which several robotic arms and instruments can be passed. Since then, several recent reports have demonstrated its feasibility in urologic surgery. Benefits to this technology include enhanced optics and ergonomics with improved cosmesis and a decrease in incisional hernias and post-operative complications. Yet, the technology has not been perfected with user complaints related to poor triangulation, difficulty with retraction and arm clashing, and decreased assistant access. In response to these concerns, the da Vinci SP 1098 was designed by Intuitive Surgical as a platform designated specifically for R-LESS surgery. The system is still in preclinical phase, however, users report enhanced triangulation and arm clashing. The role of this robotic platform in the armamentarium of the practicing urologist has not yet been defined.

In sum, robotics has revolutionized urologic surgery both by refining current surgical techniques, as well as allowing urologists to tackle more complicated interventions that would otherwise be addressed in the classic open fashion. As more medical specialties adopt the robotic platform, the benefits of this technology will only continue to grow in the coming years.

Chapter 254

ROBOTIC SURGERY FOR UROLOGIC MALIGNANCIES

Jay D. Raman, MD

Urology, Penn State Health Milton S. Hershey Medical Center,
Hershey, PA, US

1. INTRODUCTION

Urologic surgery for both benign and malignant etiologies has evolved towards minimally invasive approaches when feasible and safe. Conventional laparoscopic surgery represented the initial minimally invasive breakthrough with demonstrable benefits across various disease processes with respect to perioperative morbidity, convalescence, and return to standard activities of daily living [1]. Laparoscopy, however, is not without challenges including a relatively steep learning curve, need for advanced surgical skill set, as well as dexterity to operate straight, non-articulating tools with two dimensional optical viewing [2].

In that regard, robotic-assisted laparoscopic surgery or robotic surgery represents the next iteration of minimally invasive surgery (MIS) with benefits for urologists both comfortable and not comfortable with conventional laparoscopy. Although initially developed with primary intent for cardiac surgery, robotics was rapidly embraced by urologists for a realm of surgical indications. Specifically, those urologic surgeons familiar with laparoscopy noted improved visualization with the three dimensional resolution coupled with precise movement using articulating instrumentation. Furthermore, urologists with more rudimentary MIS skills found the platform more easily adaptable with a flattened learning curve [3].

When considering applications for urologic malignancies, the robotic approach has been applied to prostate cancer (radical prostatectomy), bladder cancer (radical cystectomy), kidney tumors (partial and radical nephrectomy), upper-tract urothelial carcinoma (radical nephroureterectomy or segmental ureteral resection), as well as other less common malignancies [2].

In the subsequent sections, we briefly discuss the experience with prostate cancer but thereafter the attention is focused on robotic applications and data for two of these urologic cancers which have demonstrated the greatest areas of growth over the past five years. We specifically choose these two index robotic operations both due to growth but also the related

scientific work that has been expended to better define their relative roles in the disease management process. In that regard, we focus on robotic assisted radical cystectomy (RARC) and robotic assisted partial nephrectomy (RAPN).

2. ROBOTIC-ASSISTED RADICAL PROSTATECTOMY

When historically considering urologic oncologic robotic procedures, prostate cancer surgery demonstrates the most extensive experience with the longest existing track record [4]. Radical prostatectomy (RP) can be performed by an open or laparoscopic approach (with or without robotic assistance). Contemporary studies have highlighted an incredible diffusion of robotic-assisted radical prostatectomy (RARP) increasing from 0.3% of all cases in 2001 to over 85% of cases after 2010 [5]. Population-based reports as well as meta-analyses all demonstrate that RARP compares favorably with the open approach with equivalent oncologic and potentially superior quality of life and functional outcomes following surgery [6].

As surgical experience for RARP has evolved, the indications are identical as open radical prostatectomy particularly with consideration of high risk patients with locally advanced (T3-T4) tumors without obvious clinical metastasis. The critical elements of RARP entail achieving a negative surgical margin, maintenance of the external genitourinary sphincter (for urine continence), and preservation of the neurovascular bundles (when possible and appropriate) to aid in recovery of sexual function [7]. Of the 3 outcomes described above, cancer control is paramount with biochemical recurrence patterns and survival rates being key indicators although requiring a relatively long duration of follow-up to reach such endpoints. Therefore, positive surgical margin rate (PSM) remains a relatively easily measured oncologic outcome that reflects the quality of the cancer surgery. In RARP series originating from centers of excellence, the overall PSM rates range between 9-15% for pT2 disease and 25-35% for pT3 disease [8]. Pre-operative imaging with a 3-Tesla pelvic MRI obtained 4-6 weeks after prostate biopsy provides an excellent adjunctive imaging study to better delineate surgical anatomy at time of prostatectomy [9].

The apical prostatic dissection is one of the most challenging steps at RARP owing to several factors [7]. Firstly, the apex of the prostate is surrounded by a number of structures including the pubic bone, dorsal venous complex, neurovascular bundles, and rectourethralis muscle all of which require preservation thereby greatly limiting the physical working space. Secondly, the apex of the prostate often lacks a true capsule thereby blurring some of the anatomic planes of dissection. Finally, individual patient anatomy is most variable in this location with the potential for an apical notch (distal beak of prostatic tissue protruding above or below the urethra) that can contribute to a positive margin [10]. Critical steps to maintain functional urethral length include cold or athermal division of the dorsal venous complex with hemostasis prior to dividing the urethra. Such a maneuver keeps a relatively bloodless plane critical for maximizing urethral length without yielding a positive surgical margin [11].

Finally, nerve preservation is a critical element to maintain erectile function following RARP. The neurovascular bundles carry both vascular elements as well as nerve tissue that emanate from the pudendal artery and course within the periprostatic fascia. Experienced RARP surgeons have suggested using the periprostatic venous plexus as an anatomic

landmark to establish dissection within various fascial compartments enveloping the prostate [12]. Thus, depending upon the clinical and tumor characteristics of individual cases, dissection may be carried out in one of three planes including the intrafascial plane (complete nerve sparing), the interfascial plane (partial nerve sparing) or extrafascial plane (non-nerve sparing). Furthermore, the use of hydrodissection techniques may further develop these planes whilst hypothermic cooling can reduce any potential thermal injury to these key anatomic structures [13]. Details on these technical refinements have been summarized well in several contemporary reviews of the literature [14].

In summary, RARP now represents the surgical standard of care for prostate cancer with clearly defined surgical technique and measurable oncological and functional outcomes. The precision and magnification afforded by the robotic platform have contributed to improved surgical margin status, continence, and potency outcomes.

3. ROBOTIC-ASSISTED RADICAL CYSTECTOMY (RARC)

Bladder cancer represents 4.7% of all new cancer cases in the United States [15]. In 2017, there were estimated to be 79,030 new cases of bladder cancer with 16,870 cancer-related deaths thereby making it the second most common urologic cancer following prostatic malignancy [15]. Radical cystectomy with extended pelvic lymph node dissection and urinary diversion represents the standard of care for patients with muscle-invasive bladder cancer (MIBC) as well as high risk non-muscle invasive bladder cancer (NMIBC) who are at risk for disease recurrence or progression [16]. Oncologic outcomes particularly when used in combination with appropriate perioperative systemic chemotherapy remain superior to other modalities when considering local control, recurrence-free, and disease-specific survival [17].

Radical cystectomy (RC) is a complex operation in a relatively comorbid patient population. Complication rates even from regionalized centers of excellence are greater than 50% despite streamlined pathways that govern post-operative care for these patients [18]. As a consequence, the potential role of MIS approaches for RC have been broached in recent years with early case reports highlighting feasibility as well as the potential for less blood loss, decreased post-operative rates of ileus, and a potential shorter hospitalization [19, 20].

3.1. Indications for RARC

The indications for RARC are similar to that for open radical cystectomy and are clearly delineated in the AUA/ASCO/SUO/ASTRO and EAU treatment of non-metastatic muscle invasive bladder cancer guidelines [21]. In summary, RC is an appropriate therapy for organ-confined (cT2) or locally advanced (cT3/cT4) N0M0 bladder cancer. Additionally RC can be an appropriate initial treatment option for some patients with: 1) high-grade, NMIBC (Ta/T1/Tis) that recurs following treatment with intravesical *Bacillus Calmette-Guerin* (BCG); as well as 2) intermediate-risk papillary urothelial carcinoma disease not readily controlled by transurethral resection and adjuvant intravesical therapies.

It must be acknowledged that patients who are candidates for RARC represent a highly selected population when compared to open RC counterparts. Specifically, the presence of

locally advanced disease (cT4), morbid obesity with a body mass index (BMI) > 35, and bulky lymphadenopathy all represent relative contraindications for the robotic approach. Furthermore, patients with uncorrected coagulopathy and significant prior abdominal surgery and/or radiotherapy present as higher risk cases with potential for prolonged operative times, wound healing issues, or perioperative complications [22]. Such cases typically should be reserved for higher volume surgeons with extensive experience.

3.2. Basic Operative Steps

Although differences may exist amongst surgeons, some of the basic operative steps are shared in common. Access into the abdominal cavity can often be performed by the Veress needle technique with a long 12mm trocar placed at the umbilicus. On the patient's left side, two 8 mm trocars are typically inserted. The first is located approximately 10 cm from the midline port on a line between the umbilicus and the anterior superior iliac spine. The second is located approximately 3 fingerbreadths above the left iliac crest. On the patient's right side, 3 trocars are typically inserted. An 8 mm robotic trocar is inserted approximately 10 cm from the midline port on a line between the umbilicus and the anterior superior iliac spine. A 15 mm trocar is inserted several fingerbreadths above the right iliac crest and a 12 mm trocar is inserted in the right upper quadrant, roughly at the location of where the urostomy is going to be sited to be used both for this case and then for creation of the urostomy. The robotic surgical system is docked after placing the patient in the steep Trendelenburg position.

The sigmoid colon is mobilized out of the deep pelvis and posterior peritoneum is opened yielding dissection of both vasa and seminal vesicles. After dividing the vascular supply of these structures, the posterior perirectal fat plane is dissected. Thereafter, ureters are identified as they course over the iliac vessels. Dissection is performed leaving a judicious amount of adipose and areolar tissue for vascularity. This ureteral dissection is carried to the level of the superior vesicle artery at which point the ureter is doubly clipped and divided with distal tip sent for frozen section.

Thereafter, the lateral aspects of the space of Retzius are exposed with the lateral pedicles of the bladder divided using clips or mechanical stapler devices. At this juncture the bladder dissection is complete to the level of the prostate and the anterior aspect of the space of Retzius is exposed. A 0-Vicryl suture is used across the dorsal venous complex with dissection all the way down well beyond the apex of the gland and to the urethra. The urethra transected with a clip the bladder side to avoid any spillage prior to doing that. Meticulous extended pelvic lymph node dissection is then performed with appropriate urinary diversion performed thereafter.

3.3. Early RARC Series

Early experience with RARC had several common themes. Many were single center series that were performed by high volume robotic surgeons as a “proof of concept.” Namely, these groups sought to demonstrate that RARC was a safe procedure although direct comparisons to an open RC cohort typically were not performed. Additionally, many of these

reports entailed an extracorporeal urinary diversion (ECUD) as opposed to an intracorporeal urinary diversion (ICUD).

One early such series emanated from the University of North Carolina as reported by Pruthi and colleagues [23]. In this series of 100 consecutive RARC operations, the authors focused on pathologic and perioperative outcomes. The majority of the patients had cT1 or cT2 tumors and over 60% had an ileal conduit urinary diversion. This group highlighted favorable perioperative outcomes with a mean EBL of 271cc, OR duration of 4.6 hours, and length of stay of 4.9 days. Notably, 85% of patients in this group were discharged by day 4 or 5 after the operation. Furthermore, complications occurred in 41% of their cohort (8% major complications) with no mortalities within 90 days of surgery.

Other groups have further delved into the perioperative outcomes of RARC and have concluded comparable outcomes to ORC. Specifically, a study comparing postoperative complications in 83 RARC versus 104 ORCs suggested lower rates of major complications (17% vs. 31%) in the MIS cohort. Furthermore, on logistics regression analysis RARC was associated with lower 30 and 90 day post-operative complications [24]. Similar observations were noted in a more recent prospective cohort comparison of 158 radical cystectomy patients undergoing ORC ($n = 52$), laparoscopic RC ($n = 58$), or RARC ($n = 48$). This study noted that RARC had the lowest transfusion and complication rate with the shortest length of stay, albeit with longer OR duration [25].

Juxtaposing this perioperative data highlighting safety were early reports of oncologic outcomes. Specifically, in 2013, Xylinas et al. reported on early to intermediate oncologic outcomes in 175 patients at a median follow-up of 3 years [26]. Recurrence-free and cancer-specific survival at 2-, 3-, and 5-years were 67%, 63%, and 63% (for RFS) and 73%, 68%, and 66% (for CSS), respectively. Appropriately, these authors concluded that RARC with ECUD was a safe and efficient approach with acceptable mid-term oncologic control. Similar work by Dasgupta et al. further emphasized that intermediate oncologic outcomes with RARC are encouraging with an overall and recurrence-free survival of 95% and 90%, respectively, at a maximum of 3.5 years post-surgery [27]. These numbers appear particularly favorable although may be a function of relatively short duration of follow-up interval.

3.4. Data from the International Bladder Cancer Robotic Consortium

With these promising initial data, the logical extension was multicenter collaborations formally referred to as the International Robotic Cystectomy Consortium (IRCC). This consortium consisted of 22 high volume surgeons from 15 international community and academic practices who pooled their retrospective RARC data to report on key metrics and index measures. In 2013, this group critically appraised complications following RARC and noted 30- and 90-day complication rates of 41% and 48%, respectively [28]. The majority of these complications were minor (Clavien I and II). Finally, the 30- and 90-day post-RARC mortality rate was 1.3% and 4.2%, respectively.

Surgical margin status is a known risk factor for urothelial cancer recurrence. The IRCC reported an overall positive soft tissue margin rate of 6.8% which increased with pathologic stage [29]. Specifically, the positive margin rate was 1.5% of pT2 disease, 8.8% for pT3 cancer, and 39% for pT4 cancers. These data warrant particular attention as a positive soft

tissue margin for urothelial carcinoma likely portends a high likelihood of disease recurrence and potential progression.

Lymphadenectomy for urothelial carcinoma can be both diagnostic as well as therapeutic. However, the feasibility, technical nuances, and lymph node (LN) yield of an extended pelvic lymph node dissection have surfaced as concerns with the robotic approach. Fortunately, with improved surgical experience (likely gaining improved confidence in operating around the vascular structures) as well as refinements in the surgical systems, concerns with RARC LN dissection have largely been placated. Specifically, both a non-randomized comparative study and a randomized prospective trial have suggested equivalent LN yield between the open and robotic cohorts [30, 31]. Additionally, the IRCC concluded that the rates of lymphadenectomy at RARC for advanced BC are similar to those of ORC series [32]. In this collaborative series, 83% of patients underwent a LND with a median of 17.8 LN removed. Interestingly (but likely not surprisingly), they hypothesized that learning curve may play a role in RARC LND with a volume relationship noted with surgical experience.

Finally, it is essential to highlight that the above metrics all lead back to the adequacy of oncologic control of RARC. In that regard, in 2015 the IRCC published long-term oncologic outcomes on a cohort of 743 bladder cancer patients with a median follow-up of 67 months [33]. Here, the authors noted a recurrence-free, cancer-specific, and overall survival of 67%, 75%, and 50%, respectively. Collectively, these data from a large collaborative (albeit retrospective) further supported that RARC was not compromising outcomes for bladder cancer patients.

3.5. Prospective, Randomized RARC vs. ORC Studies

While the above-mentioned studies (both single and multicenter) are promising, the optimal comparative studies are prospective, randomized trials.

In 2010, Nix and colleagues from the University of North Carolina published on prospective RARC vs. ORC trial with the primary endpoint being LN yield and secondary endpoints being perioperative and other pathologic outcomes [30]. When considering the primary study endpoint of LN yield there was equivalence (19 vs. 18 LN harvested), although many of the secondary endpoints favored the RARC approach. Specifically, RARC cases had lower EBL ($p < 0.0001$), shorter time to flatus ($p = 0.0013$), time to BM ($p = 0.0008$), and lower use of in-house analgesia in morphine equivalents ($p = 0.0044$).

In 2013, a similar size study designed as a non-inferiority prospective study was published by Parekh et al. [34] In this study, the primary endpoints included margin status, LN yield, and perioperative outcomes while the secondary endpoints included quality of life (QOL) and functional recovery. The RARC group was noted to have lower EBL (400 vs. 800cc, $p = 0.003$) and a greater number of patients had a shorter length of stay ($p = 0.03$). These observations were similar to that noted by the previously mentioned Nix study. This group, however, also carefully annotated patient QOL and well-being every 3 months from the time of surgery to 1-year after using the Functional Assessment of Cancer Therapy: Vanderbilt Index [35]. Interestingly, they noted no differences in any of the well-being domains (personal, functional, social, emotional) at any of the time points between the two groups. These suggested equivalence in modalities although was surprising in the absence of quality of life benefit from the minimally invasive approach.

More recently, the Memorial Sloan Kettering (MSKCC) group published their clinical trial of 60 RARC vs. 58 ORC with the primary endpoint being 90-day Clavien Grade II –V complications [36]. As with the prior studies, secondary endpoints were also incorporated and included high grade complications, OR duration, patient QOL, and cost. In contrast to the prior randomized studies, the experience from MSKCC yielded an exclusively negative study noting no differences in complications (62% RARC vs. 60% ORC), lower EBL but longer OR duration for RARC, and without pathologic differences. Furthermore, in this study, the mean hospital stay was 8 days in each arm, no differences in QOL scores at 3- and 6-months post-surgery, and the RARC approach was costlier across all types of urinary diversion.

The final single center prospective randomized trial was the CORAL trial which was published in 2016 by Khan and colleagues [37]. This study differed from the prior studies in that it was a three-arm trial comparing 20 RARC vs. 20 ORC vs. 20 LARC. Similar to prior studies, the primary endpoint was 30- and 90-day complications with secondary endpoints being perioperative clinical and pathologic outcomes and QOL. Interestingly, in this study, there were endpoints that favored each of the different approaches with some challenges in how to reconcile such observations. In particular, ORC had a significantly greater 30-day complication rate than LRC (70% vs. 26%), but no significant difference when compared to RARC (70% vs. 55%). Ninety-day complications were not different between any of the cohorts. Finally, the RARC group had the longest OR duration, the ORC had the longest time to oral intake, and LRC had the highest rate of disease recurrence. It is unclear how to reconcile these latter noted differences.

3.6. Future Directions

Thus far, RARC has been proven to be technically feasible with similar perioperative and oncologic outcomes when compared to ORC. Future directions are largely three-fold in nature to better define the role of RARC in the treatment of the MIBC patient.

The first critical element, which has already occurred but not fully reported, is evaluating RARC versus ORC in a larger prospective study. As one can discern from the prior section, the previous studies are small and have variable primary and secondary endpoints which confound the ability to fully synthesize the data. The recently completed RAZOR trial may help address this question [38]. This prospective, randomized multicenter trial evaluated outcomes from 350 patients (175 in each arm) undergoing RARC or ORC with the primary endpoint being oncologic non-inferiority at 2-years and secondary endpoints being perioperative and pathologic outcomes, functional recovery, and QOL. Early data that was recently presented at the 2017 American Urologic Association (AUA) annual meeting suggests that the RARC group had shorter hospital stay (6.5 vs. 7 days, $p = 0.023$), lower EBL (363 vs. 829 mL, $p < 0.0001$), less intraoperative (13.6% vs. 33.6%, $p < 0.001$) and post-operative (25.6% vs. 41.0%, $p < 0.001$) transfusions. Conversely, ORC had a shorter OR duration (361 min vs. 425 min, $p < 0.001$) and a lower positive soft tissue margin rate (4.5% vs. 10.6%, $p = 0.042$). There were no differences in extensiveness of LND, complications, final pathology, or 2-year progression free survival (80.2% RARC vs. 79.1% ORC, HR 0.80, $p = 0.31$). Final data are still pending, and these will define the role to a greater degree.

The second element is teasing out whether the method of urinary diversion may impact the potential benefits of RARC. Specifically, it can be argued that the data to date suggests

equivalence of RARC and ORC although almost all of these series utilized an extracorporeal urinary diversion (ECUD). Perhaps a totally intracorporeal approach (ICUD) may afford the complete benefits of MIS? In 2014, Desai and colleagues published on a series of 132 totally robotic intracorporeal neobladder creations after RC at two high volume centers of excellence (USC, Karolinska) [39]. These authors observed a mean operative time of 7.6 hours, EBL of 430cc, and hospital duration of 11 days highlighting the challenges and advanced skill set needed. Also in 2014, the IRC consortium compared ICUD versus ECUD in a cohort of 935 RARC patients [40]. Specifically, 167 ICUD were compared to 768 ECUD with comparison of perioperative and pathologic outcomes. Interestingly, these authors noted no differences in operative duration. ICUD patients had a longer hospital duration (9 vs. 8 days, $p = 0.086$) but also a lower complication rate (OR 0.68, $p = 0.02$). Clearly, the surgical reconstruction of diversion is a key metric of consideration when looking at RARC going forward. Nonetheless, at centers of excellence, the volume of ICUD procedures continues to grow [41].

Finally, further analysis of cost is needed to define the role of RARC. In 2014, Leow et al. performed a propensity-matched comparison of morbidity and costs of RARC and ORC using the premier prospective database between 2004 and 2010 [42]. In this mismatched cohort of over 34,000 ORC versus 2100 RARC, the authors concluded higher 90 day costs for RARC primarily attributable to OR duration and supplies. In a decision analysis model, however, the group clearly demonstrated that if OR duration and LOS decreased below certain thresholds, the RARC approach had lower associated costs. The size mismatch in cohorts highlights the early RARC experience, and such cost consideration merit further discussion as experience matures [43].

4. ROBOTIC-ASSISTED PARTIAL NEPHRECTOMY (RAPN)

Kidney cancer represents 3.8% of all new cancer cases in the United States [15]. In 2017, there were estimated to be 63,990 new cases of kidney cancer with 14,400 cancer-related deaths resulting in it being the 3rd most common type of urologic malignancy. The rates of kidney cancer have continued to increase over time from 7.1 cases per 100,000 persons in 1975 to 15.2 cases per 100,000 in 2014 [15]. Despite this increase in incidence of kidney cancer, survival rates have improved with 5-year relative survival rates increasing from approximately 50% in the 1970s to over 75% in the more contemporary era [44].

Although the rise in kidney cancer incidence is multifactorial, a principal contributing factor is the incidental diagnosis of smaller renal masses (SRMs) on axial cross-sectional imaging [45]. These SRMs are generally smaller tumors (as their name implies), more indolent in nature, and readily managed with excellent long-term survival rates. The American Urologic Association (AUA) recently released revised guidelines to better standardize the management of patients with small renal tumors [46]. These guidelines largely focus on the management of localized tumors ≤ 4 cm (cT1a) or 4-7cm (cT1b) in size. Furthermore, the key elements of the guidelines focus on the use of partial nephrectomy irrespective of surgical approach (open or MIS).

The 2017 AUA Guidelines highlight that urologists should prioritize the use of PN when possible for the cT1a renal mass owing to the superior renal function outcomes (when compared to radical nephrectomy), excellent oncologic control, and comparative oncologic

outcomes to radical nephrectomy (RN) for similar size tumors. Emphasis is placed on using PN in patients with an anatomic or functional solitary kidney, bilateral renal tumors, a history of familial kidney cancer, baseline chronic kidney disease (CKD), or proteinuria. Suggestion is also made for PN in patients at risk for declining kidney function including moderate or severe hypertension, diabetes mellitus, recurrent urinary stone disease, or obesity. Finally, the guidelines underscore that cancer control through negative surgical margins is paramount while effort should be made to maximally preserve renal function by optimizing residual functional renal parenchyma and minimizing the duration of warm ischemia. In summary, PN is indicated for tumors ≤ 7 cm in size whenever technically feasible even in the presence of a normal contralateral kidney.

4.1. Indications for RAPN

Historically, PN was exclusively performed via the open approach. With the increased familiarity of MIS originating with the original laparoscopic nephrectomy by Clayman and colleagues, experience has continued to grow and expand [47]. Indeed, both pure laparoscopy and a hybrid robot-assisted laparoscopy have increasingly been used for PN. Admittedly, a barrier for laparoscopic partial nephrectomy (LPN) is that it is a challenging procedure requiring both complex oncologic extirpation and reconstruction while working on a highly vascularized organ with the goal of minimizing warm ischemia time (WIT). For example, in a single surgeon experience of 800 LPN performed by an experienced laparoscopist, Gill et al. reported a mean WIT of 32 minutes for the first 500 procedures with a WIT of under 20 minutes in only approximately 15% of cases [48]. Furthermore, the complication rates were almost 25% in the first 275 cases with a reduction to 15% in the subsequent 289 cases.

For these reasons as well as the widespread diffusion of robotic technology, RAPN has increasingly been adopted in the surgical management of SRMs. Indeed, it can be argued that the robotic platform has simplified and accelerated two critical elements of the operation; namely, dissection through the renal parenchyma and renorrhaphy. Additionally, the use of a robot facilitates the dissection and mobilization of the kidney, especially for the approach to the upper pole and posterior tumors, which is often challenging for standard laparoscopy. Collectively, these have contributed to a significant growth of RPN in practice and perhaps even the technique of choice when the technology and expertise is available [49].

4.2. RAPN vs. LPN

Prior to delving into the specific nuances of RAPN, it warrants consideration to first discuss comparisons between the two MIS approaches. Overall, one can summarize the data by emphasizing that high volume expert surgeons note good experience with both modalities although RAPN appears to yield shorter operative duration, longer warm ischemia (WIT), and less blood loss. A few of the most pertinent studies are highlighted below.

An early single institution study by Aron and colleagues involved a matched-pair analysis of 24 cases (12 RAPN and 12 LPN) controlling for several different clinical and tumor-related variables including age, gender, BMI, performance status, as well as tumor size and location [50]. Although a relatively small study, these authors noted comparable perioperative

outcomes including operative duration, blood loss, WIT, as well as hospital duration. In addition, when considering renal function outcomes 3-months after surgery (as measured by eGFR), the results were also comparable. It is important to note that this series emanated from high volume experienced surgeons with expertise in LPN.

A much larger series which was comparative and multicenter in 2009 by Benway et al. noted similar observations albeit with conclusions that mild favored the robotic approach [51]. In particular, in this retrospective study of consecutive LPN (n = 118) and RAPN (n = 129) performed by one of three surgeons, no significant differences were noted between the groups. Subset analysis based on complexity revealed that tumor complexity had no effect on operative time or estimated blood loss for robot assisted partial nephrectomy, although complexity did affect these factors for laparoscopic partial nephrectomy. In addition, for simple and complex tumors robot assisted partial nephrectomy provided significantly shorter warm ischemic time than laparoscopic partial nephrectomy (15.3 vs 25.2 minutes for simple, $p < 0.0001$; 25.9 vs 36.7 minutes for complex, $p = 0.0002$).

More contemporary data continues to favor RAPN when feasible and available. In 2011 Pierorazio and colleagues from John Hopkins evaluated outcomes and the learning curve for 150 patients undergoing RAPN (n = 48) or LPN (n = 102) by a single surgeon [52]. These authors noted that RAPN appeared to have shorter operative duration (150 vs 182, $p < 0.001$), lower WIT (13.3 vs 15.3, $p < 0.001$), and less EBL (118 vs 206, $p = 0.005$) compared with LPN. Furthermore, following a learning curve of approximately 25 cases, the transition from LPN to RAPN was not associated with immediate benefits. Additionally, a subsequent series of approximately 500 minimally invasive PN procedures has further underscored these findings and observations [53]. In particular, Khalifeh et al. reviewed 261 RAPN compared to 231 LPN and noted that the robotic group was significantly more morbid (Charlson comorbidity index 3.75 vs 1.26), included more complex tumors (R.E.N.A.L. score 5.98 vs 7.2), and had lower operative (169.9 vs 191.7 minutes) and warm ischemia (17.9 vs 25.2 minutes) time, intraoperative (2.6% vs 5.6%, each $p < 0.001$) and postoperative (24.53% vs 32.03%, $p = 0.004$) complications, and positive margin rate (2.9% vs 5.6%, $p < 0.001$). Finally, these authors noted a greater percentage of RAPN cases achieved the “trifecta” defined as a combination of warm ischemia time less than 25 minutes, negative surgical margins, and no perioperative complications (58.7% vs 31.6%, $p < 0.001$).

Additionally, recently reported systematic reviews and meta-analysis further compared outcomes of LPN and RAPN. The power of such systematic reviews is pooling data from a larger number of sources although the quality of data that is input into the analysis can drive the results. Specifically, Froghi and colleagues performed a meta-analysis of 6 non-randomized comparative studies collectively including over 250 patients and noted that perioperative outcomes were similar between modalities. [54] Specifically, six studies matched the selection criteria. In all, 256 patients were analyzed (40% RPN and 60% LPN). There was no significant difference in EBL ($p = 0.12$, 95% confidence interval [CI] -12.01 to 104.26). Similarly, there was no significant difference in WIT between the groups ($p = 0.23$, 95% CI -15.22 to 3.70). Also, LOS ($p = 0.22$, 95% CI -0.38 to 0.09) and overall postoperative complication rates were not significantly different between the groups ($P = 0.84$, 95% CI -0.05 to 0.06). Subsequently, Aboumarzouk et al. performed a similarly designed study including 7 non-randomized observational studies [55]. This analysis included over 300 and 400 cases of RAPN and LPN, respectively, and noted that RAPN was associated with significantly shorter WIT. Specifically, there was no significant difference between the two

groups in any of the demographic parameters except for age. There was no difference between the two groups regarding operative times ($p = 0.58$), estimated blood loss ($p = 0.76$), or conversion rates ($p = 0.84$). The RAPN group had significantly less warm ischemic time than the LPN group ($p = 0.0008$). There was no difference regarding postoperative length of hospital stay ($p = 0.37$), complications ($p = 0.86$), or positive margins ($p = 0.93$).

Taken together, these data underscore that while LPN is technically feasible, the results of RAPN are favorable both in the novice and experienced surgeon. As such, RAPN has increasingly become the modality of choice for minimally invasive partial nephrectomy. In fact, when one evaluates population-based studies such as that originating from the Nationwide Inpatient Sample (NIS), the adoption of LPN has not been widespread, being adopted in only 9% of all the PN cases performed in the US from 2008 to 2010 [56].

4.3. Nuances of RAPN Surgical Technique

One of the inherent challenges in critically evaluating RAPN outcomes is the variations in technical elements of the procedure that are individually reported as outcome measures of the index procedure. These are discussed in further details in the subsequent sections with the hope of addressing each of these in a greater degree of isolation. Prior to delving into these details, basic steps of the operative procedure are outlined. Following induction of anesthesia, patients have a urethral catheter and are placed in the flank up position. Veress needle insertion is performed to insufflate the abdomen and a 12mm trocar is placed approximately 15cm from the costal margin. After confirming the absence of metastatic disease, the following trocars are then inserted: two 8 mm trocars upper quadrant and left lower quadrant as well as one or two 12 mm trocars were inserted in the upper and lower midline.

The colon is mobilized off the medial surface of the kidney with identification of the psoas muscle, ureter, and gonadal vessels. The ureter is dissected off the psoas muscle permitted dissection towards the main renal hilum. The hilar vessels are delineated through confirmation with preoperative imaging. The lesion is then localized with confirmation and depth ascertained by use of intraoperative ultrasonography.

Depending upon lesion complexity, tumors are excised either by clamping the renal artery, vein, both, or neither. Renal repair is performed in two layers with distinct closure of the collecting system. Fat is then tacked over the defect. Hemostatic agents can be used but are often not necessarily while incurring excess cost.

4.3.1. Transperitoneal vs. Retroperitoneal RAPN

The surgical approach (transperitoneal versus retroperitoneal) is the first of these RAPN modifications which merits discussion. In short, each has the potential advantage and likely its own role when considering tumor location, lesion complexity, patient body habitus, and prior surgical history. To date, RAPN is usually performed through the transperitoneal approach due to familiarity with the intraperitoneal anatomy and working space of surgical instrumentation. Of note, however, is the potential advantages of the retroperitoneal approach which avoid bowel and visceral structure manipulation, direct access to the kidney and hilar vasculature, and ease of dissection for posterior tumors. Although comparative studies of surgical approach are limited (and likely flawed), a recent meta-analysis concluded that, in

appropriately selected patients, the retroperitoneal approach can shorten the operation time, reduce the estimated blood loss and shorten the length of hospital stay [57]. These authors concluded that the retroperitoneal approach may be equally safe and be faster compared with transperitoneal partial nephrectomy.

Indeed, as described above, the ideal approach is likely a balance of surgeon comfort and lesion location. An anterior hilar lesion is likely best managed by a transperitoneal approach whilst a posterior upper pole tumor is more easily accessed by staying in the retroperitoneum.

4.3.2. Method of Hilar Control

One of the historical tenets of kidney tumor resection involved clamping of the main renal artery and vein thereby reducing blood loss during incision into the kidney. Such principles seek to create a relatively bloodless field with the vascular clamps removed following repair of the defect. The concept of early unclamping following the closure of the inner medullary defect initially reported by Gill and colleagues (and subsequently other authors) has permitted a reduction in the procedural warm ischemia time [58].

This concept of decreasing the WIT has spawned increasing reports of “zero ischemia” or “off-clamp” RAPN. Initial focus with this off-clamp technique initially focused on tumors with lower lesion complexity (as measured by RENAL, PADUA, or C-index nephrometry scores) and demonstrated both good renal preservation as well as acceptable perioperative outcomes [59]. Versions of this “zero ischemia” approach has even included systemic reductions in blood pressure to induced a relative hypotensive state during the resection process [60]. Obviously, while both feasible and tenable, the latter of these approaches does raise concerns with regards to regional and central operative hypotension.

Perhaps the more readily adopted technique (particularly for more complex tumors) is the selective or super-selective clamping of tertiary or higher-order arterial branches to create an ischemia microenvironment in the tumor and adjacent parenchyma without compromising blood supply to the remainder of the kidney [61]. Such techniques require superior pre-operative axial imaging notably a CT scan or MRI with three-dimensional reconstruction of the kidney vasculature thereby allowing potential dissection of the secondary, tertiary, and subsequent branches tracking towards the tumor which can be clipped or controlled with vascular bulldog clamps [62]. Ancillary real time imaging with near-infrared fluorescence imaging allows for visualization of vascularized versus devascularized sections at time of tumor resection thereby providing immediate feedback regarding the accuracy of the selective clamping [63].

It is important to note that “selective clamping” as well as “off-clamp” RAPN are technically challenging even for the high-volume robotic surgeons. Indeed, when employed successfully, the outcomes data have elements that are favorable. Specifically, there appears to be better short-term renal preservation with superior eGFR measurements at both discharge as well as months after the operation. Additionally, volumetric measurements of the renal parenchyma on axial CT or MRI imaging suggest improved preservation when compared to the use of global renal ischemia. This, however, appears to come at a cost with reports of potentially longer operative duration, operative blood loss, as well as need for transfusion [64]. Thus, although very promising, vascular microdissection and super-selective clamping remain a challenge outside of centers of excellence.

Finally, one interesting surgical iteration or variant of the unclamped partial nephrectomy is a hybrid endovascular and robotic/laparoscopic approach [65]. In this setting, an endovascular radiology approach is used to occlude the tumor vessels after which the LPN or RAPN proceeds with tumor ischemia achieved from the embolization process. The early data are interesting in that the contrast dye load does not appear to negatively impact the renal function of either kidney. The biggest challenge of such an approach is the need for a purpose-built suite capable of both interventional radiology and robotic or laparoscopic surgery.

4.3.3. Additional Technical Aspects of RAPN

Presently, intraoperative ultrasonography is a critical element for margin identification in renal neoplasms which are endophytic or extending deep into the urinary collecting system. Furthermore, robotic ultrasound probes can be used, which are directly controlled by the console surgeon [66]. Intraoperative ultrasonography is a key technical component for all robotic renal surgeons irrespective of lesion complexity.

Renal repair or renorrhaphy can be performed by one of several techniques. Several groups advocate closure of the inner medullary defect without parenchymal closure to avoid ischemia that may devascularize these segments [67]. Other groups advocate a sliding clip technique with either interrupted or horizontal mattress closure of the parenchyma [68]. All of these closure modalities warrant investigation through volumetric analysis on axial imaging to better estimate degree of renal parenchymal preservation [69].

Finally, various fibrinogen coagulation enhancers and tissue sealants can be applied on the defect, along with bolsters. However, their usefulness is debatable and costs may not be insignificant. In 2016, Maurice and colleagues reviewed 544 RAPN procedures of which hemostatic agents (HA) were used in 240 (44.1%) [70]. The mean number of agents per case was 1.4 ± 0.73 , including 77 (14.2%), 52 (9.6%), and 39 (7.2%) cases in which cellulose, fibrin, or gelatin-based agents were used alone, respectively, and 72 (13.2%) cases in which multiple agents were used. The mean cost of HA per case was $\$488 \pm 421$. Nearly 90% of cases were performed by surgeons who were beyond their learning curves. Overall, 13 (2.4%) patients were transfused, and the median hemoglobin decline was 2.2 g/dL (IQR, 1.4–3.0 g/dL). On univariate analysis, HA use and type of HA were not significantly associated with blood transfusion ($p = 0.20$ and $p = 0.29$, respectively), but were associated with hemoglobin decline ($p = 0.01$ and $p = 0.02$, respectively). The authors concluded that hemostatic agent use does not alter postoperative bleeding outcomes after RAPN, suggesting that their routine use in this setting merits reconsideration.

4.4. Outcomes of RAPN

Outcomes analysis of RAPN is challenging to analyze as an amalgam due to inherent variability in surgeon experience, technique, lesion complexity, and patient driven factors. Therefore, one of the optimal methods of analysis is to look at various different types of clinical scenarios and attempt to examine these somewhat distinctly.

4.4.1. Multicenter Studies

Before diving into specific scenarios, multicenter studies do provide some framework and high-level view of RAPN outcomes. Although imperfect, multicenter studies do provide some context for RAPN in the setting of being high volume referral centers of excellence. In 2015, Lista and colleagues investigated the margin, ischemia, and complications (MIC) system achievement rate within a population of patients managed by RAPN [71]. In this multicenter study of 339 patients with cT1 masses, cancer control was defined as the absence of positive surgical margin, ideal threshold of warm ischemia time (WIT) was considered ≤ 20 minutes, and safety was defined as the absence of major complications. In this study, the overall MIC rate was 67% with a median WIT of 17 minutes (range, 7-51 minutes) and positive surgical margins were found in 22 patients (6.5%). Overall postoperative and major complication rates were 14.5% (n = 49) and 3.8% (n = 13), respectively. Similar complications data was reported by Spana et al. in a multicenter series of 450 RAPN operations [72]. In this dataset, the overall complication rate was 15.8% with the majority of complications being minor Clavien I or II, and under 5% of complications being Clavien III or greater.

4.4.2. Hilar Renal Tumors

Hilar renal tumors present as an anatomically more complex lesion with a greater risk of perioperative bleeding and urine leak given proximity to vascular and urinary drainage tube structures. With respect to hilar tumors, several authors have demonstrated that RAPN can be a relatively safe option in this patient cohort with comparable outcomes to tumors in different locations. Specifically, in 2011, Dulabon and colleagues compared outcomes of 41 patients with hilar tumors versus 405 patients with tumors in non-hilar regions [73]. The authors noted that the hilar tumors required a longer WIT for excision (26.3 min vs. 19.6 min, $p < 0.0001$) albeit without any differences in pathologic or perioperative outcomes. These authors therefore concluded that RAPN is a feasible approach for hilar tumors without adverse sequelae in experienced robotic surgeons. Similar work by Eyraud et al. in a single institution series compared 294 non-hilar tumors with 70 hilar tumors [74]. Analogous to what was noted in the above work, surgeries for hilar tumors were associated with longer operative duration (210 vs. 180 minutes, $p < 0.001$), longer WIT (27 vs. 17 min, $p < 0.001$), and increased blood loss (250 vs. 200 ml, $p = 0.04$). However, these differences did not translate into clinical differences with regards to transfusion rates, length of stay, complications, or positive margin rates. Additionally, the longer warm ischemia time in the hilar cases did not translate to inferior renal function outcomes.

4.4.3. Larger and Complex Tumors

Tumor complexity can broadly be captured by evaluating both larger tumor size as well as those with greater nephrometry score. With regards to tumor size, two multicenter series by Ficarra et al. and Petros et al. demonstrated the feasibility of partial nephrectomy for cT1b tumors with a WIT under 25 minutes and a low rate of intraoperative and post-operative complications [75, 76]. Such findings, however, are not universally applicable across all studies [77]. Notably, tumors of greater complexity beyond size alone can be reasonably managed by robotic surgery. A single institution study of almost 50 cases with renal tumors having a PADUA score ≥ 10 (high complexity) noted a reasonably short WIT (median, 16 minutes), acceptable complication rate (4.5% intraoperative and 23% post-operative, and

good renal function outcomes (no decline in the serum creatinine level and eGFR 6 months after surgery) [78]. Obviously, much of this must be taken in the context of high volume surgeons performing these more challenging RAPN.

4.4.4. Special Situations

Traditionally, consideration has been made for the use of OPN in certain situations related to baseline CKD, multifocal tumors, solitary renal units, and other similar factors. The thought process has been the ability to potentially work at a faster speed in a hypothermic environment in these more complex situations. Admittedly, although the experience in these situations is less robust, evidence indicates that RAPN is feasible in such cases. For example, Kumar and colleagues reported on a multicenter cohort of 1197 consecutive patients who underwent RAPN of which 172 patients had preexisting CKD (estimated glomerular filtration rate [eGFR] of 15-60 ml/min per 1.73 m²) [79]. Perioperative results of 121 patients were compared against propensity score-matched controls without CKD (eGFR $\geq$ 60 ml/min per 1.73 m²). The study noted that patients with baseline CKD had a lower percentage eGFR decrease at first follow-up (-5.1 vs -10.9), which remained significant at a mean follow-up of 12.6 mo (-2.8 vs -9.1, $p < 0.05$), and they had less CKD upstaging (11.8% vs 33.1%). CKD patients were also less likely to be discharged in the first two postoperative days (39.7% vs 56.2%, $p = 0.006$) and had a higher rate of surgical complications (21.5% vs 10.7%, $p = 0.007$).

The experience with solitary (anatomic or functional) renal units is limited to expert RAPN surgeons with robust expertise. In 2013, Hillyer and colleagues reviewed outcomes of RAPN in a multi-center cohort but focused on the 26 patients (3%) with a solitary renal unit.(80) Perioperative outcomes included a median warm ischemia time of 17 minutes with two reported 2 intraoperative complications (both vascular injuries) At a median follow-up was 6 month, renal function did not change significantly as measured by estimated glomerular filtration rate (-15.8%; $p = 0.13$) and importantly none of the patients required dialysis. In this unique clinical scenario, RAPN also appears to confer an advantage when compared to other MIPN techniques. Specifically, in 2013, Panumatrassamee et al. compared 52 LPN and 15 robot-assisted RAPN procedures performed in a solitary kidney [81]. These authors noted that the median operative time (225 vs 171 min, $p = 0.02$), warm ischemia time (19 vs 15 min, $p = 0.04$) and hospital stay (4 vs 3 days, $p = 0.03$) were significantly shorter in the robotic group. There were no significant differences were found in terms of EBL, transfusions, complications, pathological results, margin status and post-operative renal function. However, long-term hemodialysis was required for three patients in the laparoscopic group (6%) and none of the patients in the robotic group. One can argue that the superior renal repair afforded by robotics may play a key role in this situation where ischemic interval may be paramount.

MIPN can also potentially be performed in patients with multiple renal masses in the same kidney. Clearly, although both LPN and RAPN have been described, patients must be counseled regarding the higher risk of open conversion. The group at the National Cancer Institute has reported on many of these cases in the setting of inherited kidney cancer syndromes. Specifically, in 2009, Boris and colleagues reported on their experience in resecting 24 tumors in 9 patients using robotic assistance. In this experience, one patient required open conversion whilst three were able to be performed without clamping the renal hilum [82]. Subsequently in 2013, Abreu et al. performed a matched-pair analysis of 66

patients (33 with multiple tumors and a similar number with a single tumor) [83]. Interestingly, EBL and WIT were similar between the groups although the median operative duration and hospital stay were longer for the multiple tumor cohort. Additionally, the complication rate was higher in the multiple tumor group (33% vs. 21%).

The final special situation that warrants mention is the role and feasibility of MIPN in re-operative tumor surgery. These cases have the potential for significant perirenal scarring and tissue planes may be obscured from prior work. One can argue that these cases should only be undertaken by high volume surgeons who are facile with operative salvage especially with risk of bleeding. In that regard, in 2008, Turna and colleagues reported on LPN in 25 cases who had previously had an OPN performed. Not surprisingly, the WIT (36 minutes) and EBL (215mL) were greater than what is observed for *de novo* MIPN. Nonetheless, patients recovered well with no intraoperative complications reported and a 12% postoperative complication rate [84]. More recently, Autorino et al. reported on 12 tumors removed in 9 patients of which one third of patients had a solitary renal unit. The median (range) RENAL nephrometry score for the resected masses was 7 (4-8). The warm ischemia time was 17.5 min and in three of the nine patients an unclamped procedure was performed. No intraoperative complications were registered, whereas only two minor complications occurred postoperatively. There were no renal unit losses and all surgical margins were negative [85].

CONCLUSION

Robotic assisted surgery for urologic malignancies is increasingly becoming the standard of care. Certainly, for some indications such as prostate cancers, robotics accounts for the vast majority of index cases. In other disease processes, experience is growing with promising short-term and intermediate term data. This chapter highlights experience with robotic cystectomy for bladder cancer and partial nephrectomy for kidney tumors. Future work is needed to define the role across a greater number of index procedures.

Chapter 255

APPLICATIONS OF ROBOTIC-ASSISTED SURGERY IN UROGYNECOLOGY

Sarah A. Huber^{1,*}, MD and Patrick J. Culligan^{2,†}, MD

¹Department of Urology, Weill Cornell Medicine,
New York, NY, US

²The Center for Female Pelvic Health, Department of Urology,
Weill Cornell Medicine, New York, NY, US

INTRODUCTION

The field of urogynecology focuses on the treatment of female pelvic disorders, the most common of which are pelvic organ prolapse and stress urinary incontinence. The etiology of these problems are multifactorial, with multiple genetic and environmental factors, including childbirth, obesity, smoking, and prior hysterectomy [1, 2]. Wu et al. calculated a weighted prevalence of 25% for one or more pelvic floor disorders in US women and predicted a doubling in the prevalence by 2050 due to an aging population [3]. There is an 11-19% lifetime risk of women undergoing at least one operation for urinary incontinence and pelvic organ prolapse with a 29.2% risk for reoperation in this cohort [4, 5]. In 2010, it was estimated that approximately 300,000 surgeries for pelvic organ prolapse were performed in the US, and this is expected to increase as the prevalence rises [6].

Minimally invasive approaches to the treatment of urogynecologic problems have had a growing role in surgical management. Compared to vaginal and open abdominal surgery, laparoscopic urogynecologic procedures have consistently better or at least non-inferior outcomes with lower complication rates, blood loss, postoperative recovery, and incision cosmesis [7, 8]. Since the first laparoscopic Burch colposuspension was performed in 1991, there has been a growing trend toward the utilization of laparoscopy, particularly with

robotic-assistance, as the mode of choice for certain urogynecologic procedures [9–12]. In 2005, the FDA approved of the use of robotic applications in gynecologic surgery, and subsequently, the rate of its implementation in all fields of gynecology has increased about 25% per year [13]. Within the field of urogynecology, the addition of robotic instrumentation provides improved visualization of the peritoneal cavity and easier access to the presacral space and space of Retzius, both of which are heavily involved in standard urogynecologic surgical methods. Ob/Gyn resident training has begun to incorporate validated simulated robotic training courses into their didactics, and as a result, young physicians are completing residency with competency in robotic gynecologic surgery [14–17]. These factors, combined with the comparable outcomes and low complication rates, have encouraged urogynecologists to adopt this approach in their routine practice.

The following chapter addresses the standard approach to the more common robotic urogynecologic procedures and also discusses new trends and future innovations in robotic surgery for prolapse. We will also review the standard robotic set-up and perioperative considerations for urogynecologic surgery.

GENERAL CONSIDERATIONS

Preoperative Planning

Patient selection criteria for a robotic urogynecologic surgery versus vaginal, abdominal, or laparoscopic surgery are similar to those in other surgical fields. Factors that affect the decision to proceed with robotic surgery include patient preference, surgeon skill level, as well as the indication for surgery and other planned procedures. Other characteristics that may sway one toward robotic surgery specifically include prior pelvic surgery, concern for pelvic adhesions, and a foreshortened vagina. Although obesity may increase operative time, it does not appear to affect surgical morbidity or blood loss, and shows similar success when compared to normal-weight individuals [18, 19].

All patients should undergo the standard preoperative workup and clearance assessment as supported by ACOG and ACC/AHA [20, 21]. This includes a review of medical comorbidities with appropriate focused testing as well as a pregnancy test if indicated [22]. If a hysterectomy is planned, patients must have a current pap smear. Routine screening for occult uterine cancer is controversial due to the lower detection rate of non-endometrial histologies; however, endometrial biopsy and/or pelvic ultrasound may prove beneficial for preoperative counseling and surgical planning [23, 24]. Preoperative bowel preparations are no longer recommended for routine urogynecologic surgery, aside from procedure-indicated rectal washout in the operating room [25].

Perioperative Management

As the patient will be in steep Trendelenburg position for an extended period of time, positioning and stabilization at the beginning of the case is critical. Although there are a variety of ways to safely position patients, we have found that the use of a foam pad under the

body with neutrally-positioned arms sitting in foam-cushioned sleds adequately stabilizes and protects the patient throughout surgery. A Foley catheter is placed for continuous bladder drainage unless contraindicated for the procedure.

At our institution, we routinely place a preoperative transverse abdominis plane (TAP) block, as it has been found to significantly reduce postoperative pain [26–28]. Once anesthesia has been completed, the patient is placed in dorsal lithotomy position with the buttocks to the edge of the disassembled table. We advise the use of leg stabilizing movable stirrups (Allen or Yellowfin, Allen Medical®, Acton, MA) which protect the peroneal nerve from injury and allow for maneuvering the patient between low and high lithotomy during various stages of the surgery. In our practice, we routinely use a pneumatic sequential compression device in low-risk patients until ambulatory after surgery to prevent DVT/VTE formation. Other preventative options, including medical anticoagulation regimens and recommendations for high-risk patients, are followed in compliance with the 9th edition guidelines from the ACCP and ACOG [29, 30].

In accordance with ACOG guidelines and based on recommendations from the CDC, perioperative antibiotics are routinely administered for all urogynecology procedures as these are considered to involve clean-contaminated surgical sites [31, 32]. First-line treatments include a single-dose weight-based first-generation cephalosporin (cefazolin), clindamycin plus gentamicin or quinolone, or metronidazole plus gentamicin or quinolone with re-dosing as needed. A skin prep with chlorhexidine or povidone iodine of the abdomen is performed as well as a vaginal prep with either povidone iodine or chlorhexidine with 4% alcohol. In studies comparing vaginal preparation solutions, chlorhexidine is the more effective at reducing bacterial colony counts; however, povidone iodine is currently the more readily available option in most hospitals [32–34].

During surgery, constant communication with the anesthesia team must be maintained as the steep Trendelenburg positioning combined with the CO₂ pneumoperitoneum can place stress on the cardiopulmonary system and affect systemic vascular pressures. Older patients, longer operative times, high maximum end-tidal CO₂, and a greater number of surgical port incisions place an added risk [35]. Improved operative efficiency with close coordination with anesthesia can effectively reduce these risks, allowing for safe completion of the procedure without complication.

Trocar Placement

As the majority of urogynecologic procedures focus on the same pelvic anatomy with similar requirements for range of motion and space accessibility, the robotic trocar placement stays relatively consistent in non-complex cases. Variations to the standard port placements for each procedure will be discussed separately; however, the anatomical landmarks to guide correct placement should always be identified.

The robotic camera port typically is placed intraumbilically or supraumbilically at the level of L3 to L4 depending on surgeon preference and patient anatomy. We prefer an umbilical entry as it allows for easier specimen extraction, less pain, and better cosmesis. In obese patients, placement superior to the umbilicus may be considered, as their umbilicus tends to be more caudally displaced. Initial entry method can be left to surgeon preference; however, at our institution, we initiate entry with a Veress needle through the umbilicus

followed by CO₂ insufflation once a low entry pressure is confirmed. Once appropriate abdominal distention has been obtained, a blunt tipped trocar is placed through the extended umbilical incision through the fascia and into the peritoneal cavity with visual confirmation of correct location. When placing the trocar in thin patients, we insert it at a somewhat acute angle to avoid intestinal or vessel injury as the aortic bifurcation sits at L4 to L5 and the left common iliac vein may be aberrantly located directly below the umbilicus [36]. We typically will place a 10-12mm trocar at the start of the case to aid in specimen removal and suture or mesh insertion.

Lateral instrument port placement differs based on the da Vinci robotic version, currently in the Si or Xi format. In general, Si trocars for urogynecologic procedures are distributed in a “W” layout (Figure 1). A line is marked 16cm cephalad to the superior margin of the pubic symphysis following insufflation. Two ports are placed 9cm lateral to this mark on the right and left. A third port is placed in the left lateral abdomen 4cm superior and 3cm lateral to the umbilical camera port.

Xi port placement is in a more linear pattern with the trocars placed 8cm apart from each other along a transverse plane at the level of the umbilicus (Figure 2).

Both Si and Xi port placement includes a 3-5mm assistant port about 5cm lateral to the camera port in the right upper quadrant of the abdomen.

Figure 1. Standard trocar placement using da Vinci Si for urogynecologic procedures.

Figure 2. Standard trocar placement using da Vinci Xi for urogynecologic procedures.

When placing the lateral ports, the superficial epigastric vessels and deeper inferior epigastric vessels ideally should be identified prior to insertion. The superficial circumflex iliac artery is at risk for injury with placement of the left far lateral trocar. Another potential area of bleeding with lateral trocar insertion is the median umbilical ligament (obliterated urachus) which can have a vascular remnant.

SURGERIES FOR PELVIC ORGAN PROLAPSE

Oftentimes, patients with a symptomatic prolapse will report symptoms of bothersome vaginal pressure or a bulge that significantly affects their quality of life. In an effort to better classify the degrees of prolapse, a quantification system, known as the POP-Q, has been implemented in patient evaluation and counseling. Typically patients with Stage 2 or greater prolapse, that is prolapse at or past the level of the hymen, will be symptomatic [37]. Prolapse can manifest along the anterior vaginal wall, posterior vagina wall, or vaginal apex or cervix, often occurring together. Options for management include observation with lifestyle modifications and pelvic floor exercises, pessaries, or surgical therapy. Laparoscopic surgery has been increasingly used to address apical prolapse with concomitant anterior or posterior prolapse. Three procedures will be discussed below that have proven effective for apical suspension.

Sacrocolpopexy

Abdominal sacrocolpopexy was initially published in the literature in 1962 by Lane. At the time, he described a technique to affix the vaginal apex to the sacral promontory using a graft. Although the technique has changed over the years, the principles of a permanent attachment of the apex to the anterior longitudinal ligament at the sacrum using an implanted strengthening material has proven to be a highly effective and safe treatment, establishing it as the “gold standard” for apical prolapse repair [38, 39].

The first laparoscopic sacrocolpopexy was performed in 1994 by Nezhat with demonstrable high success rates and lower blood loss and recovery time compared to open abdominal sacrocolpopexy [40]. With the introduction of robotic assistance and the FDA approval for its use in gynecologic surgery in 2005, surgeons began to apply this technology to sacrocolpopexy. They found that robotic surgery reduced some of the technical difficulties associated with straight-stick instrument manipulation and improved visualization, particularly of the deep pelvis and sacral promontory. This enabled a more careful, precise dissection of the planes for mesh attachment which theoretically would optimize the support [41].

Technique with Concomitant Supracervical Hysterectomy

Port placement is similar to other urogynecologic procedures and depends on the da Vinci format as mentioned above. If a supracervical hysterectomy with or without bilateral salpingectomy or salpingo-oophorectomy is indicated, that will be performed first. We

typically start with monopolar scissors, bipolar Maryland forceps, and a single tooth tenaculum in the robotic instrument ports.

Figure 3. Completion of anterior vaginal wall dissection in robotic-assisted laparoscopic sacrocolpopexy. B: bladder, FB: outline of foley balloon, AVW: anterior vaginal wall.

The robotic single tooth tenaculum grasps the anterior cervix and retracts it anteriorly and cephalad toward the sacral promontory, thus supplanting the use of a vaginal manipulator. Using a mixture of sharp and blunt dissection, the anterior peritoneum is dissected away from the cervix and vaginal wall, thus safely displacing the bladder away from the areas of anterior mesh attachment. An atraumatic grasper is introduced through the assistant port and applied to the cut edge of peritoneum immediately cephalad to the bladder which is then retracted anteriorly and cephalad. This applies adequate counter-traction to allow improved visualization of the vesicovaginal plane. Dissection continues until the vaginal sulci are encountered laterally and the bladder neck is reached caudally, confirmed by Foley balloon identification (Figure 3).

Figure 4. Completion of posterior vaginal wall dissection in robotic-assisted laparoscopic sacrocolpopexy. PB: perineal body, PVW: posterior vaginal wall, R: Rectum.

The tenaculum is then used to grasp the posterior cervix which is pulled anteriorly in the direction of the pubic symphysis. After identification of the rectal reflection and the course of the uterosacral ligaments, an incision in the peritoneum is made at the cervix and carried out laterally to the uterosacral ligaments. The posterior vaginal wall is isolated from the underlying tissue via blunt and sharp dissection through the rectovaginal space. This is carried distally until the perineal body and rectal reflection is encountered (Figure 4). A robotic grasper can be gently applied to the posterior peritoneum and pararectal adventitial tissue to provide counter-traction during dissection.

Dissection of the tissue overlying the anterior longitudinal ligament is accomplished by tenting of the peritoneum, allowing safe entry to the retroperitoneal space. At this point, we allow CO₂ to enter the incised space to create tissue separation. Before proceeding further, the common iliac vein, middle sacral, and hypogastric vessels as well as the right ureter should be identified. It is important that hemostasis is optimized at this stage of the procedure; therefore, small vessels should be identified promptly and coagulated prior to transection. With blunt dissection in a mainly cephalad-caudad rather than a transverse direction, about 2cm of anterior longitudinal ligament is exposed around the level of S1-S2 which reduces the risk of sacral bleeding [42]. The superficial peritoneal incision is extended down the right paracolic gutter half-way between the ureter and colon until it communicates with the incised posterior peritoneal edge created during the posterior dissection. The 3rd arm is required to sweep the bowel to the left side and anteriorly to better visualize the space and to provide tissue counter-traction. By sweeping the colon to the left sidewall, the surgeon can effectively overlay the peritoneum against the sacral promontory to facilitate entry into the presacral space (Figure 5).

Figure 5. Dissection of anterior longitudinal ligament. ALL: anterior longitudinal ligament, MS: middle sacral vessels, U: right ureter, C: colon swept medially.

A lightweight Y mesh that has previously been cut to a length of 6 to 8 cm anteriorly and 8 to 11 cm posteriorly is passed through the camera port. In cases where there is no cervical stump, the length of the anterior and posterior vaginal arms may be shorter. Prior to passage of the mesh in to the abdomen, we loosely tie the anterior arm to the sacral arm to avoid visual obstruction from the loose mesh (Figure 6). Six CV-4 polytetrafluoroethylene (PTFE,

Origami Surgical, Madison, NJ) sutures on a tapered needle, cut to 8 inches, and one 10-inch 0 poliglecaprone (Monocryl®, Ethicon, Sommerville, NJ) suture on a tapered needle are also passed through the camera port. This can be expedited with the use of a contained laparoscopic suture delivery system which facilitates the introduction of the sutures in one pass through the camera port and allows for the assistant port to be 3-5mm (Figure 7). At this point the scissors and forceps are replaced with a large suturecut needle driver and a second large needle driver.

Figure 6. Ultra-lightweight Y-mesh with anterior arm cut to 6 cm and posterior arm to 10 cm. A loose knot is placed through the anterior arm and sacral arm.

The posterior vaginal arm of the mesh is attached to the posterior vaginal wall using permanent PTFE suture in an interrupted fashion while the cervix is under anterior traction using the tenaculum. The mesh knots are most easily placed starting with three distal sutures, taking care to avoid the rectovaginal junction while incorporating some of the fibers of the perineal body if possible. This creates a support frame along the total length of the posterior vaginal wall. Two midline sutures are placed 2cm proximally followed by two additional sutures even more proximal near the lateral borders of the dissection. Additional sutures can be applied to secure the mesh all the way to the cervix or uterosacral ligaments. It is helpful at times to lessen cervical traction when applying the most apical mesh sutures. Approximately 6 to 10 sutures should be placed on the posterior wall.

The loose knot holding the anterior vaginal arm to the sacral arm is cut, and the anterior vaginal arm is laid in the vesicovaginal space and attached to the anterior vaginal wall using permanent sutures. In order to improve visualization and create counter-traction, the tenaculum pulls the anterior cervix cephalad and the surgical assistant retracts the cut anterior peritoneal edge. Similar to the suturing of the posterior arm, three PTFE sutures are initially placed at the most distal end of the dissection around the level of the bladder neck followed by additional midline and lateral sutures at 2cm intervals moving proximally until the cervix is reached. The knots should lie anterior to the mesh and should total about 6 to 10 sutures along the anterior wall.

Once the vaginal walls and apex are secured to the mesh, the peritoneal incisions overlying this area are reapproximated using 0 poliglecaprone in a modified purse-string fashion, starting at the midline of the rectovaginal posterior peritoneal edge and then

proceeding in a clockwise fashion, incorporating the remnants of the round ligaments and anterior cut edge of the anterior peritoneum. Once the right lateral border of the peritoneal incision has been reached, the suture is taken over the mesh and the right and left edges of the rectovaginal/paracolic incised peritoneum are reapproximated. This effectively covers the vaginal arms of the mesh and begins to bury the sacral arm of the mesh inside the paracolic peritoneal tissue.

The sacral arm of the mesh is grasped with a non-crushing forceps, such as the tip-up or double fenestrated grasper and pulled toward the sacrum. The mesh is tensioned based on a vaginal exam performed by the surgical assist or primary surgeon (Figure 8). The vaginal walls should feel supported but not taut. Excess sacral mesh is cut and removed by the assistant. Two permanent sutures are placed perpendicularly through the anterior longitudinal ligament distal to the sacral promontory drop-off and back through the mesh. Care must be taken to place secure sutures through the ligament without too much depth and distal to the intervertebral disc in order to avoid intervertebral disc injury or osteomyelitis [43–46]. The remaining paracolic peritoneal incision is reapproximated using the same purse-string monofilament poliglecaprone, completely burying the mesh (Figure 9). A repeat vaginal exam is performed as well as a cystoscopy at the end of the procedure.

Figure 7. Suture delivery canister (Stitchkit®, Origami Surgical, Madison, NJ) containing six CV-4 PTFE sutures.

Figure 8. Tensioning of mesh prior to suturing down onto anterior longitudinal ligament.

Technique with Prior Total Hysterectomy

For patients with a prior total hysterectomy, a 13 x 3.5cm Breisky vaginal retractor or coated non-conductive stent (Marina Medical, Sunrise, FL) is placed into the vagina to delineate the anterior and posterior walls at the vaginal apex during dissection. We prefer these non-tapered instruments rather than an EEA sizer which only extends the vaginal apex. The bladder may be backfilled to further identify its location in order to avoid inadvertent cystotomy. Once dissection is complete, the sacrocolpopexy is performed using the same technique as above. We typically will avoid placement of sutures around the area of the previous vaginal cuff incision in order to reduce the risk for mesh exposure.

Figure 9. Completed robotic-assisted laparoscopic sacrocolpopexy with peritoneal closure.

Concomitant Procedures

Concomitant procedures can be easily performed in conjunction with sacrocolpopexy. It is now standard practice to screen patients prior to surgery for baseline stress urinary incontinence (SUI) or risk for de novo SUI. In these cases, a suburethral sling or other anti-incontinence procedure can be performed at completion of the sacrocolpopexy.

Complications

In a systematic review of 27 studies evaluating robotic-assisted sacrocolpopexy, the composite intraoperative complication rate was 3% and postoperative complication rate was 11% with only 2% classified as serious [47]. Reported complications of minimally invasive sacrocolpopexy include GI or GU injury, other bowel sequelae such as ileus, obstruction, or herniation, vascular injury, vertebral disc puncture, spondylitis and osteomyelitis, sacral nerve root injury, conversion to open procedure, and mesh erosion.

Erosion of mesh into the vagina has been estimated to occur in about 2% of robotic sacrocolpopexy cases; however, the absolute prevalence is unclear as multiple factors involved in technique and patient selection increase the risk for mesh erosion, creating variations in the published research [47]. Some of these risk factors include mesh material selection (specifically ePTFE mesh), concurrent total hysterectomy, vaginal atrophy and smoking [48, 49]. As a result, recent recommendations have advised uterine preservation or supracervical hysterectomy at the time of sacrocolpopexy when using polypropylene mesh

[50]. In fact, supracervical hysterectomy alone appears to decrease the risk of mesh erosion in laparoscopic sacrocolpopexy by about 4-fold [51]. The true risk for mesh erosion associated with transvaginal vaginal wall dissection and mesh suture is unclear with inconsistent conclusions drawn from the available literature; therefore, out of caution, we perform our entire procedure robotically without any transvaginal dissection [51, 52]. By incorporating the techniques of supracervical hysterectomy, robotic mesh attachment, and careful initial robotic dissection, we have had no mesh exposures in our practice [53].

Outcomes

Compared to other methods of apical prolapse repair, sacrocolpopexy via any approach is superior to vaginal surgery. Patients who underwent vaginal apical repair rather than sacrocolpopexy were more likely to report awareness of their prolapse after surgery (relative risk 2.11), undergo repeat surgery (relative risk 2.28), have objective recurrent prolapse (relative risk 1.89), and were at increased risk of postoperative stress urinary incontinence and dyspareunia [39]. In a single arm prospective study using ultra-lightweight mesh on 120 patients with Stage 2 or greater prolapse, there was an 89% objective success rate and 94% clinical cure rate at one year [54]. In a similar study using lightweight Y mesh, the 1 year clinical cure rate was 95% and objective cure rate was 84% [53]. Mean operative time and estimated blood loss were 148 ± 27.6 min and 51.2 ± 32 mL, respectively. A 2014 systematic review and meta-analysis in which 27 articles were included, robotic-assisted laparoscopic sacrocolpopexy (RSC) had a cumulative objective cure rate of 84-100% and subjective cure rate of 92-95% [47].

Implant Selection

Various materials have been used as the fixation media in sacrocolpopexy; however, synthetic Type I macroporous polypropylene mesh remains the most popular option due to its efficacy and availability with a low adverse effect profile. Recently, ultra-lightweight mesh (technology-density 19 g/m²) has emerged as a promising material that maintains integrity, thus guaranteeing successful outcomes, while reducing the “mesh load” on the attached tissue [53, 54]. Other non-synthetic materials can be used including fascia lata and porcine dermal graft with reasonably good outcomes. In a 12-month follow up RCT comparing porcine dermis to synthetic mesh, the anatomic cure rate was 80% versus 86% using porcine mesh or polypropylene mesh, respectively [55]. However, when a similar study was performed with fascia lata versus polypropylene mesh, the synthetic material was superior in all objective measures at one year, but showed no significant difference at 5 years with using a composite objective and subjective measure [56, 57].

In our practice, we use an ultra-lightweight mesh such as Restorelle® Y mesh (technology-density 19 g/m², Coloplast A/S, Humlebæk, Denmark) for our sacrocolpopexy procedures. Biologic materials can be considered for use in patients on a case-by-case basis, specifically for women with an increased risk for mesh exposure or who may undergo radiation treatments in the future.

Sacrohysteropexy

Sacrohysteropexy is a procedure we reserve for patients with symptomatic apical prolapse who desire future pregnancy. Similar to sacrocolpopexy, the vagina, cervix, and uterus are brought cephalad by fixation of an implant material to the anterior longitudinal ligament of the sacrum. While some techniques describe attachment of mesh to the anterior pubocervical fascia and posterior cervix at the proximal portion of the rectovaginal space via openings in the broad ligaments, we opt to attach mesh only to the posterior aspect in order to allow for unrestricted uterine expansion during pregnancy [58, 59].

Technique

The equipment is set up in a similar fashion as described for sacrocolpopexy above. A uterine manipulator is placed within the uterus and Foley catheter in the bladder. The peritoneum is incised over the sacral promontory and carried down to the anterior longitudinal ligament as described above [60]. The peritoneal incision is then extended along the right paracolic gutter toward the right uterosacral ligament for eventual mesh burying. With anterior retraction of the uterus, the rectovaginal space is entered near the level of the cervix and carried down to the perineal body. A single sheet of 5x15cm lightweight mesh is placed along the posterior vaginal wall from the perineum to the base of the internal cervical os, incorporating fibers from the distal end of the uterosacral ligaments, using interrupted PTFE sutures on a tapered needle. After appropriate tensioning via vaginal exam by the surgical assistant, the excess mesh is cut and attached to the anterior longitudinal ligament with two PTFE sutures. A 10-inch 0 poliglecaprone on a tapered needle is used to close the posterior peritoneum over the vaginally attached mesh, creating a “neo-cul-de-sac,” and the remainder of the mesh is buried under the reapproximated paracolic peritoneum.

The anterior wall and uterine body are uninvolved; however, some patients may report some pain during pregnancy that can be resolved with vaginal pessary placement to relieve downward pressure. Although anterior prolapse can be addressed using this method via apical suspension, these patients may need repeat prolapse surgery for anterior descent in the future [61, 62].

Complications

Intraoperative complications are similar to sacrocolpopexy and appear to occur in similar frequencies. An understandably low rate of vaginal mesh exposure occurs due to the uterine preservation, more limited dissection and suturing, and younger patient age. Although limited literature is available, successful pregnancies have been documented following sacrohysteropexy with no effect on mesh integrity following delivery [60, 62].

Outcomes

As sacrohysteropexy is a relatively new procedure, outcomes data is limited; however, promising results are being published. In a 2014 prospective study of 140 women with a follow up time of 1 to 4 years, 89% of patients described their prolapse as “very much” or “much” better with positive improvement in pelvic floor symptomatology and objective measurements [63]. A recent comparative study of laparoscopic sacrohysteropexy and vaginal mesh hysteropexy found similar anatomic (77% vs 80%; adjusted odds ratio, 0.48; $P = .20$)

and symptomatic (90% vs 95%; adjusted odds ratio, 0.40; $P = .22$) outcomes at one year [64]. A 5-year study of 37 patients who underwent robotic-assisted laparoscopic sacrohysteropexy showed an 81% success rate in treating uterine prolapse; however, 43% of women demonstrated some degree of anterior wall prolapse and 21.6% of women had posterior prolapse [65]. Subjective quality of life scores remained high even 5 years after surgery.

High Uterosacral Ligament Suspension

Although sacrocolpopexy is the preferred surgery for apical prolapse, other procedures can be performed if a sacrocolpopexy is contraindicated. While there are many different approaches, the only other intraperitoneal approach of any efficacy is the high uterosacral ligament suspension. In our practice, we will typically offer uterosacral ligament suspension to patients who may be undergoing radiation at some point (i.e., patients with concomitant apical prolapse and gynecologic cancer) who are having robotic surgery or for patients who need to undergo a total hysterectomy with removal of the cervix for cervical dysplasia.

Technique

After trocar placement as discussed above, the robotic patient cart is either docked between the legs or parallel to the patient's left side per surgeon preference. A 0° robotic camera is placed through the umbilical port and the remainder of the robotic arms are aligned and connected to their respective trocars. Using antero-cephalad vaginal retraction with a probe in post-hysterectomy patients or a uterine manipulator in patients still with a uterus, tension is placed on the uterosacral ligaments to improve visualization and to allow isolation of the ligaments from surrounding tissue. In patients undergoing a concomitant robotic-assisted total laparoscopic hysterectomy, this is performed prior to colpotomy while the uterus is devitalized but still attached to the connective structures. At this point, the pelvic course of the bilateral ureters is assessed, as they can come within 1 to 2cm lateral to the ligament at this location [66]. Two sutures are placed lateral to medial on the more proximal portions of each uterosacral ligament as it dives posteriorly and cephalad toward the sacrum. Our suture of choice is PTFE, but delayed absorbable suture can also be used. If a hysterectomy is performed at the same time, the colpotomy is completed and uterus and cervix removed through the vagina. The sutures are then passed through the ipsilateral pubocervical and rectovaginal fascia and embedded within the vaginal cuff tissue, avoiding full-thickness penetration through the epithelium. Open cuffs are then closed with polyglactin sutures prior to tying down the uterosacral sutures. A third row of sutures can be placed if the uterosacral ligaments are elongated and additional suspension is required. Plication of the sutures at the midline is not necessary. After tying down the sutures, the apex of the vagina should be suspended above the level of the ischial spines in a midline position. A cystoscopy should be performed prior to removal of the ports to ensure ureteral patency.

Complications

Serious complications from laparoscopic high uterosacral ligament suspension (HUSLS) are rare. The main risk of the procedure is ureteral kinking or injury which occurs in up to 11% of vaginally approached cases [67]. In a recent retrospective study by Barbier and

colleagues, there was a significant difference in rate of ureteral compromise, occurring in 10% of the vaginal procedures and 0% of the laparoscopic procedures [68]. Although the risk for ureteral injury is much lower when performed laparoscopically, likely due to improved visualization and the opportunity to incise the overlying peritoneum to “release” the ureter away from the ligament, intraoperative cystoscopy is crucial to confirm ureteral patency and function. If the ureter appears to be poorly functioning, the offending suture is removed which typically resolves problem. Other reported complications include bowel or bladder injury, hemorrhage, pelvic infection with abscess formation, vaginal exposure of nonabsorbable suture material, and dyspareunia.

Outcomes

Initial studies comparing laparoscopic to vaginal high uterosacral ligament suspension identified better objective outcomes with higher apices, better subjective symptoms, as well as a lower risk for ureteral compromise in the laparoscopic cohorts [69–72]. One study followed 133 laparoscopic patients for 2 to 7 years postoperatively, reporting a 12.8% prolapse recurrence rate, comparable than vaginal HUSLS. Of note, the tensile strength of the sutures placed vaginally or laparoscopically has been found to be equivalent, suggesting that laparoscopic suture and knot tying does not compromise the integrity of the suspension [73]. In summary, laparoscopically approached high uterosacral ligament suspension appears to be as effective as a vaginal approach with a lower complication profile.

Although uterosacral suspension can be performed with the uterus remaining in situ, known as uterosacral hysteropexy, success rates tend to be lower. A study by Bedford et al. reported objective success rates (POP-Q stage <2 in all compartments) for uterosacral hysteropexy 41% for therapeutic procedures, compared to 59% with hysterectomy plus HUSLS after a median follow-up of 2.5 years, although reoperation rates between the two were the same. Apical failures were identified in 27% of the hysteropexy group and 11% of the hysterectomy with colposuspension group [74].

SURGERY FOR RECTAL PROLAPSE

Ventral Rectopexy

Rectal prolapse with defecatory dysfunction is an under-recognized condition that is often concurrent with urogenital prolapse. In fact, 38% of urogenital prolapse patients demonstrate rectal prolapse on defecography [75]. One option for treatment of symptomatic rectal prolapse and obstructed defecation is a ventral mesh rectopexy which can be performed concomitantly with a sacrocolpopexy or other urogynecologic surgery [76].

Technique – Traditional Ventral Mesh Rectopexy

Traditional laparoscopic ventral mesh rectopexy, as described by D’Hoore et al., with robotic Si modification involves the initial placement of an infraumbilical 12-mm robotic camera port, two 8-mm robotic ports placed midclavicularly lateral to the umbilicus with a third robotic instrument port in the right flank [77]. Two assistant ports are suggested at the suprapubic region and left flank. Careful anterior rectal mobilization is performed with care

taken to spare the nerve supply. The rectovaginal septum is dissected distally to the pelvic floor just proximal to the dentate line. Mesh is sutured laterally to the pelvic floor muscles lateral to the rectum without direct rectal wall fixation. The proximal arm of the mesh is attached to the sacral promontory similar to sacrocolpopexy. Nonabsorbable suture is used for fixation.

Figure 10. Completed anterior midline plication of pararectal adventitia prior to attachment to posterior vaginal wall mesh arm.

Technique – Modified Ventral Rectopexy for Concomitant Sacrocolpopexy

At our institution, we have developed a novel approach to the surgical treatment of patients with concurrent apical prolapse and rectal or posterior wall prolapse with defecatory dysfunction and distended rectum. The beginning of the case proceeds in the same method as sacrocolpopexy. However, during posterior dissection, the rectum is dissected from the lateral connective tissue down to the perineal body. Multiple interrupted 0 polyglactin sutures on a tapered needle are used to plicate the adventitia lateral to the rectum across the midline, effectively reducing the rectal caliber to a more normal size. These sutures are placed in a stepwise fashion from the perineum to the rectal reflection at the cul-de-sac, taking care to avoid incorporation of the later pelvic floor musculature (Figure 10). The Y-shaped mesh is then attached to the perineal body and posterior vaginal wall with nonabsorbable suture. The previously placed perirectal sutures are used to fasten the posterior aspect of the mesh to the anterior plication over the rectum thus making the vagina and lateral adventitial tissue to the rectum more of a unified system. The apex and anterior vaginal wall mesh is attached in the standard fashion of sacrocolpopexy, and the sacral arm of the mesh is attached at the S1-S2 segment of the anterior longitudinal ligament after appropriate tensioning. The mesh is buried under the peritoneum and other indicated procedures are performed.

Complications

In addition to the risk for conversion to open, as well as the risk for bowel/bladder/gynecologic injury, mesh erosion into the vagina or rectum as well as pelvic sepsis from mesh infection have been reported. As multiple approaches to rectopexy have been reported with limited prospective research, true complication risks are unknown.

Outcomes

As with other procedures, the adaptation to a minimally invasive approach has improved postoperative pain and shortened length of stay [78]. Additionally, laparoscopic ventral rectopexy has been found to have a shorter return bowel function and lower morbidity. A long-term follow up study identified a 7% recurrence rate at 5 years and 11% rate at 10 years after laparoscopic rectopexy [79]. A comparative study between 44 robotic-assisted ventral mesh rectopexy patients and 74 conventional laparoscopic ventral mesh rectopexy showed a significant difference in postoperative obstructed defecation symptoms in favor of the robotic approach; however, 6-month recurrence rates were similar at 6.8% and 4%, respectively [80]. A recent small randomized controlled trial of robotic or conventional laparoscopic ventral rectopexy showed no difference in anatomical or functional changes with a significant reduction in descent of the anorectum and vaginal apex with straining in both groups [81].

SURGERY FOR STRESS URINARY INCONTINENCE

Burch Colposuspension

Also known as Burch urethropexy, Burch colposuspension serves as an effective anti-incontinence procedure when a midurethral sling is contraindicated for bothersome stress urinary incontinence. Given the excellent outcomes and safety profile of the midurethral sling procedures, we tend to only offer a Burch colposuspension to patients who are likely to undergo pelvic radiation in the future, such as patients with a known gynecological cancer. Although first described by Burch in 1961, the later Tanagho modification emphasizing removal of retropubic fat to allow for fibrosis was an important development that has been widely adopted and will be described here [82, 83]. Although the initial entry into the space of Retzius can be achieved via an extraperitoneal approach robotically, the more commonly used approach for robotic-assisted surgery has been transperitoneally; therefore, we will focus on that technique [84].

Technique

Robotic instruments are inserted and aligned as previously described, and a Foley catheter is placed in the bladder. Other procedures can be performed prior to colposuspension; however, in cases with concomitant sacrocolpopexy, tensioning and fixation to the sacral promontory should be performed after completion of the colposuspension.

The bladder may be backfilled with 300mL sterile water (diluted methylene blue can also be used) in order to identify the superior boundary of the bladder dome, although this is usually not necessary. The obliterated medial umbilical ligaments are identified as the lateral borders of the dissection plane and the space of Retzius is entered using posterior and cephalad retraction of the overlying peritoneum which is incised about 2-4cm cephalad from the bladder dome. A mixture of blunt and sharp dissection with monopolar scissors and bipolar Maryland forceps is used to open the space toward Cooper's ligaments distally, aiming for the posterior-superior aspect of the pubic symphysis. At this point, the backfilled bladder is drained. Hemostasis is important during dissection as pooled blood in the space can severely obstruct visualization of the paraurethral and paravaginal tissue. The dissection

should proceed distally and laterally with no midline cutting in order to avoid urethral injury or injury to the dorsal vein of the clitoris. However, excessive lateral dissection can injure the obturator neurovascular bundle. Dissection is complete when the pubic symphysis, bladder neck, Cooper's ligaments, vagina, and arcus tendinous fasciae pelvis can be seen.

Figure 11. Placement of Burch colposuspension sutures (courtesy Miklos and Moore Urogynecology, Georgia).

The urethrovesical junction can be best visualized with medial retraction of the bladder and anterior-cephalad digital vaginal pressure by the surgical assistant. Nonabsorbable ePTFE double armed sutures (Gore-Tex®, Gore, Flagstaff, AZ) are placed on the vaginal wall at the level of the bladder neck with care taken to avoid penetration into the vaginal epithelium. We recommend taking a double bite of vaginal tissue to ensure good tension distribution along the wall. A second pair of nonabsorbable sutures are placed on either side, cephalad to the previous sutures. All four sutures are placed through their corresponding ipsilateral segments of Cooper's ligaments. Vaginal pressure is released by the surgical assistant and the sutures are tied down with the knots sitting on top of the ligament, leaving about 1.5cm of distance between the paravaginal fascia and Cooper's ligament (Figure 11). If too tight, this can lead to postoperative urethral obstruction. A cystoscopy is performed at the end of the procedure after desufflation to assess for bladder or urethral injury.

A paravaginal repair can be performed at the same time if indicated for anterior wall prolapse. While placing the Burch sutures, three additional stitches can be placed between the vaginal wall and arcus tendinous fasciae pelvis and fibers of the obturator internus muscle at 1 to 2 cm intervals until the posteriorly directed defect is closed.

Complications

Reported perioperative complications of laparoscopic Burch colposuspension have included injury to the urinary tract or bowel, vessel damage requiring transfusion, and infection including an abscess in the space of Retzius. Similar to the open approach, postoperative outcomes can include detrusor overactivity, voiding dysfunction, urethral obstruction, fistula formation, pain, or posterior compartment prolapse. It has been estimated that approximately 2% of laparoscopic cases are complicated by an injury to the lower urinary tract which is predominantly cystotomy to the bladder dome [85]. The overall complication

rate of laparoscopic colposuspension is much lower than via laparotomy. However, it is imperative that cystoscopy be performed intraoperatively in order to promptly identify and address injury, as early detection is associated with decreased morbidity [86].

Outcomes

In a randomized controlled trial from 2004, seventy-two patients underwent either tension-free vaginal tape (TVT) or laparoscopic colposuspension with a mean follow up of 20.6 months [87]. Although the study noted the presence of urodynamic stress incontinence at 12 months post-surgery in 18.8% of the colposuspension group compared to 3.2% in the TVT group, they did report improvement in the number of incontinent episodes per week in both groups. In a long-term follow up study with a median 65 months duration, 58% of colposuspension patients and 48% of TVT patients reported urinary incontinence at 4-8 years after surgery which did not meet significance [88]. However, the true advantage of the midurethral slings lies in the low complication rate with rapid recovery and low cost, causing it to become the gold-standard treatment for stress urinary incontinence.

However, if a Burch colposuspension is indicated, a laparoscopic or robotic-assisted laparoscopic approach is preferred [87–89]. A study by Kitchner et al. showed non-inferiority between laparoscopic and open colposuspension with objective cure rates at 24 months of 70.1 and 79.7% and subjective cure rates of 54.6% and 54.9%, respectively [90]. However, open colposuspension has been noted to have greater blood loss, greater risk of urinary retention, and a longer hospital stay than a laparoscopic approach [91]. A 10-year study of outcomes following laparoscopic versus open colposuspension noted a deterioration in subjective cure rates at 6 months at 10 years of 71% to 52% in the laparoscopic group compared to 67% to 36% in the open group [92]. Although data is limited on robotic outcomes, one can assume that the laparoscopic findings would correlate given the similar approach.

VESICOVAGINAL AND VESICOUTERINE FISTULA REPAIR

Urogenital fistulas are devastating conditions that affect women's health and quality of life significantly. Whereas traumatic vaginal and cesarean deliveries are the most common cause of vesicovaginal and vesicouterine fistulas globally, in the US, unidentified or incompletely repaired bladder injuries at the time of gynecologic surgery are the primary causes. Fistulas can be repaired vaginally, abdominally, or laparoscopically. The intent of the fistula repair is to obliterate the non-anatomic communicating tract between the two organs. Standard practice dictates waiting 3 months after the causative injury to improve tissue quality prior to surgery. Interestingly, about 12% of fistulas naturally resolve within that period and surgery is not indicated [93].

Technique – Vesicovaginal Fistula Repair

At the start of the procedure, we recommend stenting of the fistulous tract via passage of the stent cystoscopically followed by vaginal retrieval of the passed end with uterine packing

forceps. A Foley catheter is not used during the procedure. The robotic portion of the procedure proceeds by placing the trocars in the layout described in the beginning of the chapter with parallel or side-docking recommended. If pneumoperitoneum is compromised by the fistula, then a lubricated laparotomy sponge can be placed in the vagina. The vesicovaginal space is carefully dissected similar to the methods applied in sacrocolpopexy. Dissection is carried down until the stent is visualized and the defect is fully isolated from the proximal and distal tissue (Figure 12). If the vesicovaginal plane is difficult to visualize due to inflammation, then an O'Connor transvesical approach can be performed by bivalving the bladder until the fistula tract is seen [94, 95]. The walls of the fistulous tract are sharply removed from the surrounding healthy tissue to improve the quality of the reapproximated tissue. In general, the use of cautery is limited in order to avoid tissue devascularization or necrosis. If the fistula is located in the midline, then closure is unlikely to cause any ureteral kinking. However, if lateral, ureteral stenting may be considered prophylactically.

The bladder defect is closed with interrupted 2-0 polyglactin sutures in two layers. The first layer is a full-thickness reapproximation with the second layer serving as an imbrication layer. The integrity of the repair is tested by filling the bladder with 400-500mL of sterile water or saline which can be diluted with methylene blue. The vagina is closed with interrupted braided delayed absorbable suture in layers and should be hemostatic at the completion of the defect closure.

The peritoneal incision made at the beginning of the procedure to access the vesicovaginal space is closed with 0 poliglecaprone in order to protect the repair from intrusion of the bowel. Alternatively, an omental flap can be placed between the bladder and vaginal suture lines; however, this is not advised in women who are planning future pregnancy. At the end of the procedure, a cystoscopy is performed and an extended Foley catheter is placed. If the fistula repair is in close proximity to the bladder neck and could be in contact with the Foley catheter, then a suprapubic catheter should be considered as an alternative. If there is concern for bleeding or infection, then a drain may be considered postoperatively.

Figure 12. Completion of vesicovaginal space dissection and identification of fistula sutures (courtesy Miklos and Moore Urogynecology, Georgia).

Technique – Vesicouterine Fistula Repair

The overall dissection technique is similar to a laparoscopic intraperitoneal approach for vesicovaginal fistula described above with the option of an O'Connor transvesical dissection as needed. As for vesicovaginal fistulas, we advise sharp excision of the tract and reapproximation of the healthy surrounding tissue in layers using absorbable sutures. An omental flap can also be considered to maintain separation of the bladder and uterine layers and improve the vascular supply. If a hysterectomy is planned, then the fistulous tract is transected between the bladder and uterine layers and excised. After completion of the hysterectomy, the bladder is repaired in two layers of interrupted absorbable suture.

Complications

The typical complications include enterotomy, conversion to open surgery, or recurrence. Rare complications of UTI, vascular injury, and lower extremity compartment syndrome from prolonged lithotomy have also been reported [96]. Postoperatively, patients can develop incontinence and de novo urinary urgency although the true risk of this has not been extensively studied.

Although rare, GU fistulas may develop in areas of tumor necrosis following localized radiation therapy. It is imperative to biopsy the fistula tract prior to repair as these areas are at high risk to have tumor recurrence.

Outcomes

Numerous factors have been associated with better success rates of genitourinary fistula repair. These include surgeon expertise, prior repair, amount of fibrosis (for example, from radiation therapy), fistula size, fistula etiology, and location [97]. Minimally invasive repair for GU fistulas have a success rate of 86-100% inclusive of all simple and complex fistulas [96, 98]. When compared to abdominal GU fistula repair, robotic-assisted repair has been found to have a significantly less blood loss and shorter hospital stay and recovery [99]. As a result, the robotic approach is becoming increasingly popular as the route of choice.

The use of an interposition flap has been debated, specifically for patients at higher risk for failure and known compromised wound healing, such as cancer patients. Multiple flaps have been described in the literature, including omental, peritoneal, urachal, rectus abdominus muscle, perisigmoid fat, porcine graft, and epiploica [100–102]. To date, there have been no prospective comparative studies evaluating the use of flaps. However, surgeons have reported excellent outcomes without flap usage, so its utility is unclear [103–105].

In the case of vesicouterine fistulas, the impact of a concomitant hysterectomy has not been studied extensively; however, this has been found to be a safe and effective procedure which can be offered to patients with no plan for future childbearing [106].

FUTURE INNOVATIONS IN ROBOTIC UROGYNECOLOGIC SURGERY

The role of robotic surgery in urogynecology is constantly expanding, particularly with advancements in the use of robotic surgery for pelvic mesh removal and the use of single-port robotic surgery for urogynecologic procedures.

In situations of pelvic mesh erosion into the bladder and bowel, the use of the robot has provided improved visualization of the affected areas where tissue planes are non-anatomical and often difficult to see (Figure 13). Combined approaches that utilize both robotic as well as a transvaginal, cystoscopic, or endoscopic surgical components allows surgeons to completely resect bothersome mesh with lower morbidity than an open procedure [107]. Although still in the early phases with no prospective large-scale research available given the rarity of these complications, results have proved promising.

Though relatively new to urogynecologic surgery, single-port robotic surgery has been showing encouraging results. Stemming from the success of laparoendoscopic single-site surgery (LESS), robotic single-port surgery minimizes the risk of complications from trocar placement while still providing all the benefits of robotic surgery. Additionally, the single incision site provides better cosmesis than the 5 incisions created using traditional robotic surgery. The da Vinci® Single-Site® surgery configuration involves placement of a 8.5mm camera, two 5mm robotic instruments, and a 5/10mm assistant port through a five-lumen port that can fit through a 1.5cm incision just above the umbilicus [108, 109]. Application of single-site robotic surgery in benign gynecology has shown shorter operative time, less blood loss, and lower cumulative cost compared to multiple port surgery without any difference in surgical outcomes [110]. The feasibility of single-port sacrocolpopexy has been demonstrated through case reports, but larger-scale trials are still pending [108]. The current drawbacks to robotic single-port urogynecologic surgery involve a more limited selection of instruments, particularly the unavailability of a monopolar scissor, and the difficulty with triangulation of instruments over areas of dissection or suturing [111]. As these problems resolve with newer innovations, it is likely that single-port surgery will become increasingly incorporated into urogynecologic surgery, particularly those involving midline surgery.

Figure 13. Robotic resection of sacrocolpopexy mesh following spontaneous sacral detachment.

CONCLUSION

Robotic-assisted surgery has had a tremendous impact in urogynecology, improving surgical outcomes and patient satisfaction across all metrics. We anticipate that as newer technologies develop and the urogynecology community becomes increasingly committed to the application of robotics, its utility will become even more widespread and diverse.

INTRODUCTION

The introduction of minimally invasive surgery (MIS) has represented a milestone in the management of patients affected by gynecologic malignancies. Laparoscopic and robotic techniques have reduced the rates of intraoperative and postoperative complications as well as the length of hospitalization, leading to shorter post-operative recovery period and earlier initiation of adjuvant treatments [1-4]. Despite these advantages, the diffusion of laparoscopy in gynecologic oncology has been limited by the steep learning curve, longer operative times, and limitations of the instruments when compared to laparotomy techniques. Conversely, the adoption of robotic surgery has steadily risen in the last decade. The reasons for its success can be linked to the preservation of the benefits of MIS techniques while overcoming some of the limitations of laparoscopy [5-8]. In this chapter, the origin, indications, and challenges of robotic surgery in gynecology are discussed, with a specific focus on gynecologic oncology.

1. HISTORY AND CONTRIBUTION OF ROBOTIC SURGERY IN GYNECOLOGIC ONCOLOGY

1.1. The Origin of Robotic Surgery in Gynecologic Oncology

The first reported gynecologic surgery robotic procedures consisted of a series of laparoscopic tubal re-anastomoses with robotic assistance in 1999 and 2000. Eleven cases were performed at the Cleveland Clinic Foundation with the AESOP and the Zeus robotic surgical systems (Computer Motion Inc., Goleta, CA) [9, 10]. Eight re-anastomoses were performed at the University Hospital Saint-Pierre, Belgium with the da Vinci surgical system (Intuitive Surgical Inc., Sunnyvale, CA) [11]. In 2002, the first robotic hysterectomies with bilateral salpingo-oophorectomy (BSO) were performed at the University of Texas Medical Branch using the da Vinci surgical system [12]. A robotic infracolic omentectomy, with concomitant pelvic and para-aortic lymphadenectomy for an early stage ovarian cancer was described in the same series. Subsequently, in 2003, a case of successful robotic ovarian transposition was performed with the da Vinci at the University of Nebraska Medical Center [13].

Beginning in 2004, three series of robotic-assisted laparoscopy for benign and malignant gynecologic lesions were described at the University of Michigan Medical Center [14-16]. The primary intent was to assess the feasibility of robotic surgery in a gynecologic surgical setting. Among the group of patients with malignant disease (two ovarian, one early stage fallopian tube, and four endometrial cancers), six of them successfully underwent pelvic and para-aortic lymphadenectomy, and three underwent an omentectomy with peritoneal staging biopsies. In these cases, the da Vinci robotic surgical system was repositioned from the pelvis to the upper-abdomen, without requiring conversion to laparotomy [15].

The success of this technique led to the United States Food and Drug Administration approval of the da Vinci Surgical System for clinical use in gynecology in 2005 (Figure 1). Following this, a growing number of robotic surgical procedures was reported for gynecologic malignancies, specifically in endometrial cancer, early-stage cervical cancer and ovarian cancer [17-21].

Figure 1. Timeline of the origin of robotic surgery in gynecology.

The primary purpose of the introduction of robotic surgery at Mayo Clinic was to facilitate the use of MIS in the treatment of gynecologic malignancies [22]. One of the first robotic procedures for gynecologic malignancy was performed on April 9, 2003 by Magrina et al. [20] at Mayo Clinic Scottsdale. A robotic radical hysterectomy was performed and subsequently followed by 27 similar cases performed in women affected by cervical and endometrial cancer between April 2003 and September 2006. Although the Zeus robotic system was used initially, the da Vinci Surgical System was eventually adopted in 2004. The implementation of robotic gynecologic surgery at Mayo Clinic Rochester started in 2007 with the acquisition of the da Vinci System in the Division of Gynecology in Rochester, Minnesota [23, 24].

1.2. The Contribution of Robotic Surgery to MIS in Gynecologic Oncology

Before the implementation of robotic surgery, minimally invasive gynecologic surgery had limited use in the United States (U.S.). A cross-sectional analysis of the Nationwide Inpatients Sample database demonstrated a total of 518,828 women underwent hysterectomy

for benign conditions in 2005 [25]. Among them, at that time, only 14% of the hysterectomies were performed laparoscopically, 64% were performed abdominally and 22% performed vaginally. In another study, the rate of open abdominal hysterectomies for any indication decreased from 65% in 1998 to 54.2% in 2010. The percentage of traditional laparoscopic hysterectomies increased to 15.5% in 2006 then declined to 8.6% in 2010. The rate of robotic hysterectomy quickly rose from 0.9% in 2008 to 8.2% in 2010 [26].

In the field of gynecologic oncology, the use of MIS has been rapidly increasing since the introduction of robotic surgery [27-29]. Between 2007 and 2011, 32,560 women underwent hysterectomy for non-metastatic endometrial cancer, according to the Nationwide Inpatient Sample Database [27]. The rate of patients that underwent minimally invasive hysterectomy increased from 22% in 2007 to 50.8% in 2011 due to the widespread adoption of robotic surgery (Figure 2). Similarly, the number of institutions performing MIS in more than 80% of patients with non-metastatic endometrial cancer shifted from 1.5% in 2007 to 18.9% in 2011.

The rate of MIS continues to increase. In a recent study from our group, the percentage of laparotomies performed for surgical staging of non-disseminated endometrial cancer was significantly lower than the MIS (Figure 3) [28]. In the American College of Surgeons' National Surgical Quality Improvement Project database, among the 12,283 patients included from 2008 to 2014, the percentage of laparotomies decreased from 74.3% to 26.4%, while the MIS approach increased from 24.2% to 71.4%.

Figure 2. Percentage of patients with non-metastatic endometrial cancer that underwent open, laparoscopic, or robotic hysterectomy per year [27]. Used with permission from Amanda Fader, R. Weise, Abdulrahman Sinno, et al: Utilization of Minimally Invasive Surgery in Endometrial Cancer Care: A Quality and Cost Disparity. *Obstet Gynecol*, 127 (1), 91-100, <https://journals.lww.com/greenjournal>.

A similar transition from laparotomy to MIS techniques (in particular to robotic surgery) happened at Mayo Clinic. In patients with non-stage IV endometrial cancer, the rate of open surgeries decreased from 79% in 2007 to 34% in 2012, and robotic procedures increased from 4% to 56% in the same period [24].

The same shift in surgical approaches has been seen in the management of early-stage cervical cancer. As described in the Perspective Database, among the 1894 women that underwent radical hysterectomy (RH) for cervical cancer, the rate of open RH decreased from 98% to 67% in the period 2006-2010 [30]. In contrast, laparoscopic RH rates increased from 2% to 23%, and the percentage of robotic RH grew to 10% from the first case in 2007 to 2010.

Figure 3. Trends of MIS, laparotomy and vaginal surgery for non-disseminated endometrial cancer per year [28]. Used with permission from Jvan Casarin, Francesco Multinu, Daniel Ubl, et al: Adoption of Minimally Invasive Surgery and Decrease in Surgical Morbidity for Endometrial Cancer Treatment in the United States. *Obstet Gynecol*, 131 (2), 304-311, <https://journals.lww.com/greenjournal>.

In summary, the implementation of the robotic technique, during the last decade, allowed to make the transition towards a widespread use of MIS at a national level in gynecology in the U.S.

2. ROBOTIC SURGERY FOR GYNECOLOGIC ONCOLOGY: EVIDENCE AND CHALLENGES

The advent of robotic surgery represented a paradigm shift in the surgical approach to gynecologic diseases. Since its introduction, numerous studies have been published focusing not only on the surgical outcomes and survival but also on the costs that the procedure carries. In the next paragraphs, the evidence and challenges accompanying robotic surgery in gynecologic oncology are discussed.

2.1. Robotic Surgery versus Traditional Surgical Approaches

Overall, minimally invasive procedures have shown a decrease in surgical morbidity and length of hospital stay when compared to laparotomy without a detrimental effect on oncologic outcomes [1-4, 31]. However, the clinical benefits are less evident when the two major minimally invasive approaches (laparoscopy and robotic surgery) are compared.

Since its initial development in a dry-laboratory setting, robotic surgery was able to have superior performance in several tests, specifically: surgical time, accuracy, comfort and speed of suturing, economy of motion, and operator learning curve [32-37]. The limitations of conventional laparoscopy were overcome and significant improvements were included (three-dimensional stereoscopic vision, wristed instrumentation, improved ergonomics, and minimization of the effects of hand tremors). However, when the two procedures were compared in a Cochrane review in 2014, neither approach was superior [38]. Longer surgical time but shorter hospital stay were described in patients that underwent a robotic

hysterectomy for benign disease, while a difference in rate of complications was not detected [38-41]. No safety or efficacy data was reported in oncologic patients [38-41]. The limited number of randomized controlled trials (RCTs) available for benign disease as well as lack of data for malignancy left the authors unable to draw clear conclusions.

Since that time, clinical trials have attempted to compare clinical outcomes (such as operative time, perioperative complications, quality of life (QoL), survival) and social benefits (health care system costs, length of hospital stay) of the three surgical approaches (laparotomy, laparoscopy, and robotic) for different surgical indications. Some trials ongoing at the time of this publication are outlined below.

- *LACC trial*. A biphasic RCT in patients with early-stage cervical cancer was initiated in 2008 directed by collaborators at Queensland Centre for Gynaecological Cancer (Australia) and M.D. Anderson Cancer Center (Houston, Texas) [42]. Patients are randomized between laparoscopic (conventional or robotic-assisted) RH and abdominal RH. The primary outcome is disease-free survival (DFS), while the secondary outcomes include patterns of recurrence, pelvic floor function, QoL, overall survival (OS), feasibility of sentinel lymph node biopsy, treatment-related morbidity, and costs.
- *ROBOGYN – NCT01247779*. A French trial initiated in 2010 with a primary focus on perioperative morbidity at six months in patients affected by cervical and uterine cancers who underwent laparoscopic or robotic surgery [43].
- *NCT00671827*. An observational study directed by M.D. Anderson Cancer Center initiated in 2008, with an aim to analyze the length of surgical procedures, type of surgical procedures and the perioperative complications of robotic surgery in patients with gynecologic cancers [44].
- *ROBOTHYST – NCT01526655*. A Swedish RCT comparing open abdominal and robotic hysterectomy in patients with a low stage, low grade endometrial cancer [45]. Initiated in 2012, the primary outcome is to assess the perioperative QoL for patients. The secondary aims are six-week post-operative complications, evaluation of tissue damage, effects on the immune system, and the impact on health care system costs.
- *NCT02292914*. A Brazilian randomized clinical trial compares robotic surgery with traditional surgical approaches in patients with different tumors (including uterine cancer) [46]. Initiated in 2014, the primary aim is measurement of postoperative complications with secondary outcomes including ICU and hospital length of stay, operative time, QoL, OS and DFS.

2.2. Costs of Robotic Surgery

Robotic surgery costs and sustainability in the current health care system have been major obstacles since the introduction of the surgical modality. The costs of robotic surgery are impacted by direct costs (purchase of the robotic system, maintenance, disposable instrumentation), and indirect costs (extended operating time, reduction of efficient operating room (OR) utilization). Moreover, an increase in the costs can be seen anytime an indication for modality use is broadened without taking into account the actual benefits for the patients.

As an example, after the introduction of robotic surgery in a subset of patients affected by prostate cancer, a shift from non-surgical to surgical treatment was seen without any measurable benefit to patients in regards to outcomes and QoL [47].

In order to validate the cost-effectiveness of a surgical procedure, a variety of models can be conducted [24, 48-51]. A decision analysis was performed for patients diagnosed with endometrial cancer and costs were compared between open, laparoscopic and robotic surgical procedures. Three models were utilized for this purpose: a societal perspective model, a hospital perspective model with robot costs, and a hospital perspective model without robot costs [48]. The first two models included the costs of purchasing and maintaining a robotic system, while in the third model the hospital has previously purchased the robot and this cost was not included in the analysis. Only the first model included the costs of lost wages for patients and patient's caregivers. In all three models, the lowest costs per patient were associated with laparoscopic procedures (\$10,128, \$6,581 and \$6,581 for first, second, and third models respectively). In contrast, the costs per case for robotic surgery were \$11,476, \$8,770 and \$7,478. In the societal model, robotic surgery would become the most cost effective approach in the presence of either a reduction of the disposable material costs (Figure 4A) or proof of a most prompt return to daily activity for patients could be provided (Figure 4C). Instead, robotic surgery would be the least cost effective if case volume was insufficient (in this specific analysis, less than 13 cases per month, Figure 4B). In both of the other two models, robotic costs would be equal to or less than laparoscopic costs, if the costs of robotic disposable material were decreased.

Figure 4. Comparison of different surgical approach costs in the societal perspective model. The total cost of each surgical method is represented on the Y-axis. The variables of the X-axis are below each figure [48]. Used with permission from Jason Barnett, John Judd, Jennifer Wu, et al: Cost comparison among robotic, laparoscopic, and open hysterectomy for endometrial cancer. *Obstet Gynecol*, 116 (3), 685-693, <https://journals.lww.com/greenjournal>.

An analysis conducted using the Perspective Database focused on the association between hospital and surgeon robotic procedure volume and costs of robotic surgery [52]. A cohort of 10,906 patients who underwent minimally-invasive hysterectomy for endometrial cancer was assessed. When fewer than 5 robotic cases have been performed, the cost of robotic surgery procedures for the hospital is \$10,469. When greater than 50 robotic procedures have been performed, the cost to the hospital decreases to \$9,256. In the same way, a reduction of costs varied based on surgeon volume: for surgeons whose previous

volume was fewer than 5 cases, average cost was \$10,252. For surgeons whose previous case volume was more than 50 cases, average cost was \$7,955.

A recent retrospective study from Mayo Clinic compared 251 patients with endometrial cancer who underwent robotic surgical staging to 384 open surgical staging procedures (timeframe: 2007-2012) [24]. Although the anesthesia and OR costs were significantly higher in the robotic group, the costs related to the post-operative period (assessed 30 days postoperative) were significantly lower in the robotic group (\$19,128 vs. \$20,389 for open surgery). Although open techniques were associated with shorter operating times, when compared to robotic cases, there was an increase in the length of hospital stay, postoperative complications, perioperative transfusions, and readmission rate. Furthermore, as expertise increased over the study period, the operative time and the length of stay significantly decreased for the robotic. These improvements may positively influence the actual costs of the robotic surgery.

Although these results appear encouraging, the final analysis presented some limitations. In the first analysis, complications and readmission rates were not included in the models [48]. In the second analysis, pre-operative characteristics of the patients and tumors were not taken into account [52]. The Mayo Clinic study carries the usual intrinsic biases of non-randomized, single-institution retrospective studies, and did not analyze indirect and amortization costs [24].

It should also be noted that at its introduction, laparoscopy was initially considered more costly than laparotomy for gynecologic procedures. [53]. Similar to arguments against robotic surgery today, laparoscopy was initially scrutinized for increased costs related to disposable instruments (compare to Figure 4A). Hopefully, a change in the costs can be expected in the near future, and ongoing and future trials will likely yield more comprehensive results.

2.3. Technical Issues in Robotic Surgery for Gynecologic Oncology: The Learning Curve

The learning curve starts with development of proficiency in OR set-up, patient positioning, bedside assisting, functional port-placement and robot docking [54]. Current debate revolves around techniques and parameters to assess surgeon proficiency in robotic surgery [55].

In gynecologic oncology, the learning curve for robotic surgery was mainly studied in endometrial cancer cases. The number of surgical procedures needed to achieve proficiency and efficiency was investigated in the first 105 robotic endometrial cancer staging surgeries at the Ohio State University [56, 57]. They defined “proficiency” as the number of procedures after which the operative time curve began to level out. “Efficiency” was described as the number of procedures after which the operative time curve plateaued. The time from patients’ entrance into the OR to incision, skin to skin time, and console time significantly decreases with the increasing number of the robotic procedures. Proficiency was gained on average after 20 cases. The estimated blood loss and the lymph node yield during lymphadenectomy were not significantly different between the first 20 cases and subsequent cases. The rate of conversion to laparotomy was higher in the first 50 cases [56]. In a more detailed analysis of the first 79 robotic surgical staging procedures for endometrial cancer, it was demonstrated

that each part of the surgical procedure required a different number of cases to gain efficiency (Table 1) [57]. However, for the case as a whole and each individual portion, the only significant variation in operative time was between the first twenty cases and the subsequent cases. The lymph node yield, estimated blood loss and length of hospital stay were not different with increased surgical robotic experience.

At the Renown Regional Medical Center in Reno, Nevada, the first 122 robotic procedures and the first 122 laparoscopic procedures were compared in patients who underwent hysterectomy and lymphadenectomy for endometrial cancer [58]. Analysis demonstrated that 49 cases were necessary to gain proficiency in the laparoscopic group, versus 24 cases in the robotic group. The total operative time and blood loss were significantly lower after 24 robotic cases were completed. A varying number of cases were described in order to gain proficiency in the robotic surgery group for each portion of the surgical procedures (Table 1). Furthermore, robotic surgery was associated with a lower rate of conversion to open procedures, smaller volumes of blood loss, fewer major complications, and shorter length of hospital stay. After comparison, the two learning curves for the two minimally invasive approaches favored robotic surgery. Although robotic and laparoscopic surgery have shown a difference in the learning curve in dry-laboratory settings [32, 59], the previous laparoscopic experience of a surgeon may have influenced the learning curve for robotic surgery in the clinical setting [57, 58].

Table 1. Number of procedures required to gain proficiency and efficiency in robotic surgery for endometrial cancer patients. NA, not available; OR, operating room

Procedures	Proficiency [58] (Number of procedures)	Efficiency [57] (Number of procedures)
Hysterectomy	8	78 (including cuff closure)
Patient OR entry to incision	NA	22
Incision to robot docking	NA	45
Port placement	10	NA
Robot docking	10	NA
Para-aortic lymphadenectomy	17	70
Vaginal cuff closure	21	77
Console time	NA	69
Patient OR entry to exit	24	70
Pelvic lymphadenectomy	55	55
Skin to skin time	NA	64

The learning curve for robotic surgery in the setting of cervical cancer has been less frequently reported [60, 61]. In a retrospective series, a single surgeon with previous laparoscopic experience performed 65 robotic RHs and pelvic lymphadenectomies [60]. A significant reduction of median skin to skin time, docking time, console time, and blood loss were observed after 28 cases without a significant difference in pelvic lymph nodes yield or length of hospital stay. In another small retrospective series of 37 cervical cancer patients, a single surgeon with previous laparoscopy experience demonstrated significantly decreased operative time and blood loss after performing a robotic hysterectomy and pelvic lymphadenectomy in 12 patients [61].

Surgeon proficiency and efficiency significantly depend on the robotic surgical team: anesthesiologists, surgical technicians, circulating nurses, and bedside assistants [62, 63]. A single institution study from 2010 compared the differences in surgical outcomes between a team containing formally trained surgical assistants and those with a team with less structured training. [63]. The robot docking time and instrument exchange time were significantly reduced in the group that received formal training and the average degree of work satisfaction was significantly higher.

2.4. Technical Issues in Robotic Surgery for Gynecologic Oncology: Patient Positioning and Preparation

Patient positioning represents an essential step in robotic surgery [54]. Once the surgical procedure is underway, undocking is required before proceeding to any change in patient's position. Interestingly, an OR table that allows moving the patient's position during surgery without undocking the robot is now available. This system permits the surgeon to move the table and the robot simultaneously to facilitate ideal exposure of the surgical field. The patient is required to be placed in the dorsal lithotomy position with the buttock at the edge of the table. Shoulder braces, chest straps, and underbody foam mattress may be used to achieve safe positioning while avoiding nerve injuries. The arms are padded and placed to the sides of the patient in the anatomically neutral position with the thumb pointing up.

Stirrups are used to facilitate leg repositioning allowing for adequate visualization of the cervix for injection of indocyanine green (ICG) in patients who require sentinel lymph nodal dissection. Allen Yellofins stirrups (Allen Medical, Acton MA) are frequently used which allow for flexion, external rotation and abduction of the hips throughout the procedure without the need for repositioning (see *Lymph node assessment*). After proper positioning, the stomach should be deflated with an orogastric tube, which is left in place during the entire operation.

Figure 5. OR configuration: position of da Vinci Si, surgical assistant, and scrub nurse. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

In gynecologic cancer cases, different configurations may be utilized in the OR to perform robotic procedures. In our institution, use of the da Vinci Xi requires positioning on the patient's left side while the da Vinci Si requires positioning at the left lower corner or between the patient's feet (Figure 5). The operative console is positioned outside the surgical field. The first assistant stands to the right of the patient while the scrub nurse/surgical scrub technician stands on the left (Figure 5).

In robotic surgery, as previously described, it is critical to have a dedicated and trained surgical team who is skilled in manipulating the robot at the bedside. The team is crucial to avoid delays and difficulties during the surgical procedure. In fact, the primary surgeon is not scrubbed in, and for this reason the rest of the surgical team must be reasonably independent in managing minor surgical issues (i.e., bedside assisting, docking and undocking, exchanging instruments, cleaning the camera, and adjustment of the pneumoperitoneum).

3. ROBOTIC SURGERY FOR GYNECOLOGIC ONCOLOGY: CLINICAL INDICATIONS

3.1. Endometrial Cancer

3.1.1. Introduction

In the U.S., the most common female genital tract malignancy is the adenocarcinoma of the endometrium, with an estimated incidence of 61,380 women and 10,920 deaths in 2017 [64]. At the time of diagnosis, 67% of women have disease confined to the uterus, and only 8% of women have a distant metastatic disease [64]. Despite these characteristics, uterine corpus cancer was the cause of 4% of estimated cancer deaths among women in 2017 and an increase of 2% in mortality rate was described from 2010 to 2014 [64]. Thus, risk stratifying patients is important for prognosis and tailoring a particular patient's therapy. Currently, the stratification of patients with endometrial cancer is based on the International Federation of Obstetrics and Gynecology (FIGO) stage and characteristics of the pathological specimen (tumor histology, differentiation grade, myometrial invasion, lymphovascular space invasion (LVSI), tumor size) [65, 66]. If the disease is resectable and without distant visceral metastases, the recommended treatment is total simple extra-fascial hysterectomy (Type A according to Querleu-Morrow classification [67] or type I according to Piver-Rutledge classification [68] - Table 6), bilateral salpingo-oophorectomy (BSO), and surgical staging [69]. In a patient with pre-operative early stage disease, a minimally invasive surgical approach is considered the standard when technically feasible [69]. Lymph node assessment is dependent on the pre- and intra-operative findings, but typically is part of required surgical staging [70]. Recently the National Comprehensive Cancer Network (NCCN) accepted sentinel lymph node (SLN) sampling as an alternative to evaluate the lymph node status without proceeding to pelvic and para-aortic lymphadenectomy [69].

3.1.2. Do Different Surgical Approaches Correspond to Different Surgical Outcomes?

Abdominal laparotomy was the traditional surgical approach for hysterectomy in cases of endometrial cancer. Many retrospective studies supported the fact that laparotomy is

associated with a decreased operative time when compared to MIS but carries higher risk of postoperative complications, higher rate of major blood loss, increase in mean hospital stay and higher costs of care [27, 71-73]. Two RCTs (LAP-2, LACE trial) and a Cochrane Database Systematic review confirmed that for patients with presumed early stage endometrial cancer, laparoscopic hysterectomy reduced operative morbidity (including lower rate of surgical site infection, transfusion, and venous thromboembolism) and length of hospital stay compared to laparotomy without jeopardizing OS and DFS [1-4, 74]. Thus, MIS is considered the standard approach whenever technically feasible [69].

3.1.2.1. Robotic Surgery versus Laparotomy

Surgical staging via robotic technique has been reported to have significantly longer operative time, but on the other hand also produced fewer complications, shorter length of hospital stay, lower estimated blood loss and transfusions, and a similar number of total lymph nodes obtained (Table 2) [49, 75-88]. As reported in Table 2, data on longer operative time in robotic surgery are discordant. In one retrospective study, 155 robotic surgical staging procedures for endometrial cancer were compared with 150 open surgical staging cases [82]. Although the rate of full pelvic and para-aortic lymphadenectomy was similar in the two groups, the skin to skin operative time was significantly lower in the robotic group. Furthermore, in the robotic group total blood loss was less, mean hospital stay was shorter, and the rate of postoperative complications (such as ileus, postoperative infections, cardiopulmonary complications, anemia, and transfusion) and readmission was significantly lower. The time from OR entry to exit was similar between the two groups. Authors of this study postulated this may be influenced by the extensive laparoscopic and robotic experience and confidence of the surgeon and of the surgical team [62, 82, 89]. In another retrospective study, optimization of port placement allowed for single docking of the robotic system throughout the entire procedure, although comprehensive para-aortic lymphadenectomy was performed [75]. The result was a reduction of the total operative time.

The Mayo Clinic experience is described in Table 2 (*Bogani, 2016* [24]). Improvement in perioperative transfusions (4.4% versus 23.2%) and readmission rate within 30 days (3.6% versus 12.8%) were observed after implementation of robotic surgery with a similar intraoperative complication rate compared to laparotomy. The rate of moderate or worse postoperative complications was 7.6% for robotic procedure and 30% for laparotomy, while the rate of severe or worse complications was 3.2% and 9.6%, respectively. The rate of conversion from robotic surgery to laparotomy was 10%. Interestingly, during the study period, the operative time and the length of stay significantly decreased for the robotic group, probably due to the increasing expertise of the surgical team.

A Swedish randomized single-institution trial (RASHEC study) was designed to explore the oncologic and surgical safety of robotic staging for presumed FIGO stage I-II high-risk endometrial cancer compared to open abdominal surgery [90]. The surgical staging consisted of hysterectomy, BSO, pelvic and para-aortic lymphadenectomy. The primary outcome was the number of dissected para-aortic lymph nodes (infra-renal para-aortic lymphadenectomy), and secondary outcomes included the number of dissected pelvic lymph nodes, the rate of perioperative complications and 30-day readmission as well as health care costs. The final protocol analysis included 96 women with similar characteristics in the two groups. The mean number of para-aortic lymph nodes was 20.9 for the robotic group, and was not inferior to the mean number lymph nodes obtained from the open abdominal surgery group (22 lymph

nodes). The mean number of pelvic nodes was lower for robotic surgery (22 lymph nodes) compared to laparotomy (28 lymph nodes), but the amount obtained with robotic approach is still considered adequate to stage [91]. Comparisons in operative time, hospital stay and perioperative complications are reported in Table 2. The robotic group demonstrated smaller volumes of blood loss, while 30-day readmission rate was similar between the two groups. The health care costs (including costs of ward care, OR, post-operative care, complication costs and amortization costs of robotic surgery) were lower for the robotic surgery cohort.

Despite a paucity of data, oncologic outcomes showed no differences between the two surgical approaches, both in DFS and OS (Table 3) [81, 85, 92, 93]. A retrospective survival analysis of 370 surgically staged non-stage IV endometrial cancers compared laparoscopy, laparotomy and robotic approaches [85]. The baseline characteristics of the patients and the number of pelvic lymph nodes obtained were similar in the three groups. The rates of DFS and OS at 18 months are reported in Table 3. No significant difference was described between the three groups.

Table 3. Survival analysis in patients with endometrial cancer that underwent surgery.
DFS, disease-free survival; EC, endometrial cancer;

In summary, robotic surgery represents a safer approach when compared to open abdominal procedures, despite the longer operative time.

3.1.2.2. Robotic Surgery versus Traditional Laparoscopy

Several retrospective studies compared surgical outcomes of these two minimally invasive approaches (Table 4) [75, 78, 79, 81, 83, 85, 94-98]. Some studies have reported robotic surgery resulting in decreased estimated blood loss, rate of transfusions and rate of conversion compared to laparoscopy. Other studies have shown an advantage of laparoscopy with a lower percentage of complications and shorter operative time compared to robotic surgery.

In a retrospective series, 103 patients with endometrial cancer that underwent robotic surgical staging were compared to two historical cohorts of 138 staging laparotomies and 81 staging laparoscopies [75]. The clinical characteristics of the patients were similar, except for a lower average BMI in the laparoscopic group compared to the other two groups. Some surgical parameters are reported in Tables 2 and 4. Robotic surgery presented a significantly higher number of harvested lymph nodes (both in pelvic and para-aortic areas), and the lowest quantity of estimated blood loss. Although a similar rate of conversion to laparotomy was reported, one of the more frequent reasons for conversion in the laparoscopic group was poor visualization. This problem was reduced in the robotic surgery cohort.

A single-center RCT was conducted in Finland from December 2010 to October 2013 aiming to compare surgical outcomes in robotic laparoscopy and traditional laparoscopy for patients with endometrial cancer [99]. Ninety-nine patients with pre-operative assessment of grade 1 and 2 endometrial cancer were randomized to one of the MIS approaches and underwent hysterectomy, BSO, and pelvic lymphadenectomy. The patients' characteristics and median number of dissected pelvic lymph nodes were similar in the two groups (23 versus 25 for laparoscopy and robotic respectively). The skin to skin operating time and the overall complication rate are reported in Table 4. The median total time spent in the OR was significantly higher for the laparoscopic group (228 versus 197 minutes). The robotic group had a higher rate of overall complications, due to the higher rate of major postoperative

complications (22% vs. 10% in the laparoscopic group). The percentage of intraoperative complication was higher for laparoscopy (8% versus 0%). These differences were not statistically significant.

Chiou, 2015 [85]	150	86	179 ±59	156 ±46	1.3	2.3	3.7 ±2.2	3.1 ±1.1	NA	NA
Mäenpää, 2016 [99] - RCT	49	50	median 170 (126-259) (range)	median 139 (86-197) (range)	24	36	2 (1-2)	1 (1-2)	10.2	0

From the few survival analyses available in the literature, the two MIS approaches seem to be comparable (Table 5) [81, 85, 92, 93, 100]. From 2003 to 2010, in a retrospective series of patients with endometrial cancer, 183 women underwent robotic surgery, and 232 underwent laparoscopy [100]. The population characteristics were similar between two groups, and the median follow-up was 38 months for the robotic group and 58 months for the laparoscopic group. During the follow-up, 14.8% of patients in the robotic group had a recurrence, while 12.1% in the laparoscopic group experienced recurrence. The patterns of recurrence were similar. The 3-year DFS and OS for robotic and laparoscopic group are

reported in Table 5. In multivariate analysis, advanced stage, non-endometrioid histology, and tumor grade affected DFS significantly, while histology and tumor grade were significant for OS. The surgical approach was not identified as an independent factor affecting recurrence and survival, in both the univariate and multivariate analysis.

Table 5. Survival analysis comparison between robotic and laparoscopic groups for endometrial cancer. EC, endometrial cancer; LPS, laparoscopy; Robot, robotic

	EC inclusion criteria	Number of patients		Estimated Survival analysis at	DFS		OS	
		Robot	LPS		Robot	LPS	Robot	LPS
Coronado, 2012 [81]	Primary endometrial adenocarcinoma	71	84	3 years	92%	83.1%	95%	100%
Cardenas-Goicoechea, 2014 [100]	Surgically staged EC	183	232	3 years	83.3%	88.4%	93.3%	93.6%
Chiou, 2015 [85]	Surgically staged EC – FIGO stage IA to IIIC	86	150	1.5 years	98.8%	91.3%	98.8%	98%

As previously reported, MIS is now considered the standard of care for the surgical staging of endometrial cancer [69]. The choice between laparoscopy and robotic surgery may be related to different factors. Although surgical outcomes of the two approaches are comparable, the advantages of robotic-surgery include motion, ergonomics, dexterity of instruments, the three-dimensional tremorless image of the operating field, higher visibility and precision, and a faster learning curve. Moreover, robotic surgery is feasible in obese women, broadening the number of patients that can undergo a minimally invasive approach for endometrial cancer [94].

3.2. Cervical Cancer

3.2.1. Introduction

Despite high incidence and mortality for cervical cancers diagnosed in less developed countries, the estimated number of new cervical cancer diagnoses in the United States in 2017 was 12,820 with 4,210 estimated deaths [64]. The striking event in the reduction of cervical cancer incidence and mortality rate was the introduction of cervical cancer screening with the Papanicolaou (Pap) test and, more recently, the HPV test [101]. Despite the widespread screening in the US, about 40% of cervical cancers are diagnosed during the reproductive age years [102]. In fact, in 2012 the second cause of cancer death among women from 20 to 39 years old was cervical cancer [103].

According to NCCN guidelines, a surgical approach is indicated in early-stage cervical cancer [104]. When a conservative or fertility-sparing procedure is not indicated, the traditional surgical approach is hysterectomy and bilateral pelvic lymph node dissection (with the possibility of considering SLN mapping) (Table 6) [104]. The type of hysterectomy depends on the FIGO stage of cervical cancer (Table 6) [105, 106]. Currently, hysterectomy is classified into four types according to the Querleu & Morrow classification system (A - D) [67, 107] or historically, into five classes (I - V) according to the Piver-Rutledge classification

[68]. The difference among the hysterectomy classes is related to the escalating radical nature of the approach (Table 6).

Table 6. Types of hysterectomy. Modified from NCCN guidelines [104].
LVSI, lymphovascular space invasion

	Hysterectomy Types		
	Simple/ Extrafascial hysterectomy (Type A)	Modified Radical hysterectomy (Type B)	Radical hysterectomy (Type C)
Indication (non-fertility sparing setting)	Stage IA1	Stage IA1 with LVSI and Stage IA2	Local disease without apparent metastasis: Stage IB1 and IB2; selected stage IIA
Vaginal margin	None	1-2 cm margin	Upper $\frac{1}{4}$ to $\frac{1}{3}$ of the vagina
Ureters	Not mobilized	Tunneled through broad ligament	Tunneled through broad ligament
Parametrium	Resected at uterine and cervical border	Divided where ureter transits the broad ligament	Divided at pelvic sidewall
Uterosacral ligaments	Divided at cervical border	Partially resected	Divided near sacral region
Bladder	Mobilized to base of cervix	Mobilized to upper vagina	Mobilized below middle vagina
Rectum	Not mobilized	Mobilized below the cervix	Mobilized below middle vagina

3.2.2. Minimally Invasive Approaches

As previously described, MIS provides a less morbid approach to gynecologic oncology surgery without endangering the oncologic outcomes. Several retrospective studies [108-116] and few randomized clinical trials [117, 118] compared laparoscopic and open RH for women with early-stage cervical cancer. In a prospective randomized phase II trial conducted in England, 15 women with FIGO stage IB1 cervical cancer with size less than 2 cm were randomized to RH via laparoscopic versus open abdominal surgery [117]. Longer operative time was described for laparoscopic surgery, but a lower median duration of bladder catheterization, median blood loss and median opiate requirement in the first 36 hours after surgery were discovered. Furthermore, laparoscopy was described as less radical compared to laparotomy, due to the lower mean resected vaginal cuff length, mean resected cardinal ligament length and mean resected uterosacral ligament length.

Until the advent of robotic surgery, the radical surgical treatment of cervical cancer was rarely performed with a minimally invasive approach in the U.S. [55, 119, 120]. In 2015, a survey was sent to the members of the Society of Gynecologic Oncology on the use of MIS in gynecologic oncology procedures [119]. Seventy five percent of the respondents indicated they utilize the robot for RH and pelvic lymphadenectomy, and indicated they have not performed these with traditional laparoscopy. The impact of MIS (both robotic and laparoscopic) in cervical cancer patients was investigated in many studies. In a retrospective study of 1894 patients with cervical cancer registered in the National Perspective Database between 2006 and 2010, 1610 underwent an open RH, 217 a laparoscopic and 67 a robotic one [30]. Throughout the study period, the rate of laparotomy decreased from 98% in 2006 to

67% in 2010. Overall, the perioperative complications were less common in the MIS group (9.2% in the laparoscopy group, 13.4% in the robotic group and 15.8% in the laparotomy group). Furthermore, the rate of transfusions (5.1% in the laparoscopy group, 4.5% in the robotic group and 15% in the laparotomy group) and the median length of stay (two days for laparoscopy, one day for robotic and three days for laparotomy) were lower in the MIS group. Unfortunately, median costs were significantly higher in the minimally invasive approaches: \$9618 for open RH, \$10,176 for the robotic and \$11,774 for the laparoscopic approach.

3.2.2.1. Robotic Surgery versus Laparotomy and Traditional Laparoscopy

Many retrospective studies compared the robotic approach with laparoscopy and laparotomy in attempt to identify the best surgical procedure for early cervical cancer management (Table 7 - 8) [30, 31, 121-145].

A retrospective multi-center study compared 491 women with early-stage cervical cancer who underwent open or robotic type II and III (comparable to type B and C) RH between 2005 and 2011 [140]. As described in Table 7, the mean operative time was longer for robotic surgery. The lymph node yield was similar between the two groups. The rate of estimated blood loss ≥ 150 ml was significantly lower for robotic surgery (20% vs. 96%), as well as transfusions rate (3% vs. 7%) and the rate of patients with a hospitalization time > 3 days (40% vs. 85%). The overall complication rate was similar between the two groups, although the percentage of moderate or worse postoperative complications was higher in the robotic group (22% vs. 18%). The intraoperative complications were higher in the laparotomy group (4% vs. 10%). The survival analysis showed similar recurrence-free survival and overall survival with a mean follow-up of 34.6 months for the robotic group and 45.2 months for the laparotomy group. The rate of recurrence was 9% for both the groups and the mortality rate was 3% for robotic surgery and 4% for open surgery.

Many other retrospective studies showed the feasibility of robotic surgery for a RH in early-stage cervical cancer in comparison laparotomy (Table 7). In one of these studies, the skin to skin operative time for type III (type C) RH was significantly shorter for robotic surgery compared to a historical cohort of open abdominal surgery and the average number of lymph nodes resected was higher in the robotic group (33.8 vs. 23.3) [121].

Studies comparing robotic and laparoscopic approaches for RH are shown in Table 8. A meta-analysis compared 1161 patients that underwent an MIS for cervical cancer with particular attention to safety and efficacy of robotic surgery in these cases [143]. No RCTs were available for the analysis. 468 patients underwent a robotic RH, and 693 underwent a laparoscopic RH. There was no difference in skin to skin operative time, the conversion rate, rate of intraoperative complications, or lymph nodes yield between the two groups. The estimated blood loss was significantly less and hospital stay was significantly shorter in the robotic group. The rate of postoperative complications, recurrence rate, and DFS were similar between the two groups. The data on resected vaginal cuff length and resected parametrial size were insufficient to perform the meta-analysis, but the two retrospective studies that described these outcomes showed similar results between the two groups [132, 133]. Two other meta-analyses reported similar results [31, 120].

In these retrospective series no difference in DFS and OS was observed between the three surgical approaches [127, 138-140, 142, 143, 145]. The results of a biphasic RCT (LACC trial) to compare MIS (laparoscopic and robotic surgery) and open abdominal RH for early-stage cervical cancer patients are expected in 2018 and DFS is the primary outcome [42, 117]. Patterns of recurrence, pelvic floor function, QoL, OS, feasibility of SLN biopsy, treatment-related morbidity and costs are the secondary outcomes.

4. NEW FRONTIERS IN GYNECOLOGIC ONCOLOGY

ROBOTIC SURGERY

4.1. Obese Patients

Obesity is one of the leading risk factors for the development of endometrial cancer [146, 147]. Traditionally, obesity was considered a relative contraindication to conventional laparoscopy due to the poor exposure of the operative field (pelvis and retroperitoneum). Recently, many studies are showing that MIS reduces the risk of postoperative complications in this subgroup of patients [148, 149].

A phase III RCT comparing laparoscopy versus laparotomy modalities for surgical staging for early-stage uterine cancer (LAP-2 study) has been completed [2, 150]. The use of laparoscopy showed a reduction of successful surgical staging and an increase of conversion to laparotomy with increasing BMI (conversion rate of 25.8% in the overall population of the study, while 57.1% in BMI ≥ 40 kg/m²). The primary clinical reason for conversion to laparotomy was poor exposure and visibility.

In retrospective series of patients with endometrial cancer, robotic surgical staging produced similar outcomes to laparotomy with fewer conversions compared to laparoscopy, even despite a higher BMI noted in those patients [75, 151]. Several studies confirmed that particularly in obese women, robotic surgery overcomes the traditional limitations of inadequate exposure of the operative field encountered in laparoscopy. It simultaneously produces similar surgical outcomes as laparotomy while reducing perioperative complications (Table 9) [80, 152-154].

A retrospective cohort of 73 patient with endometrial cancer and BMI ≥ 30 kg/m² underwent surgical management via robotic surgery or laparotomy [80]. Mean BMI was 41.9 kg/m² in the laparotomy group and 39.8 kg/m² in the robotic group. No difference was observed in the rate of lymphadenectomy performed and in the number of total lymph nodes obtained, although the median operative time was higher in the robotic cohort. The previously described benefits of robotic surgery (decreased blood loss, fewer transfusions and shorter length of hospital stay) were confirmed in this subgroup of patients. The rate of complications and the conversion rate are described in Table 9. Particularly notable was the significant difference in wound complications (4.1% in the robotic cohort versus 20.2% in the laparotomy cohort).

In another retrospective cohort study of patients with endometrial cancer and BMI ≥ 30 kg/m², 129 underwent surgical staging via robotic approach and 110 via laparotomy [152]. The rate of lymphadenectomy performed and the number of total lymph nodes obtained was similar between the two groups. In the robotic group, significantly fewer wound

complications was diagnosed (Table 9), but more vaginal cuff complications were described (4.7% versus 0%). The total amount of other complications (transfusions, renal failure, 30-day hospital readmission, ICU admission, ileus and small bowel obstruction) was significantly lower in the robotic group.

With the increasing prevalence of obesity in the population [155], two other subgroups of patients have significant clinical relevance in endometrial cancer: the morbidly obese women ($\text{BMI} \geq 40 \text{ kg/m}^2$) and the super morbidly obese women ($\text{BMI} \geq 50 \text{ kg/m}^2$) [153, 156-161].

A retrospective cohort of 426 women with endometrial cancer and $\text{BMI} \geq 40 \text{ kg/m}^2$ underwent primary surgery at Memorial Sloan Kettering Cancer Center, New York. Two hundred and ninety nine cases were performed via laparotomy, 125 via MIS (robotic or laparoscopy) and two via a vaginal approach [156]. This study demonstrated that in this group of patients, the rate of MIS grew from the 6% in the “laparoscopy era” (1993-2007) to the 57% during the “robotic era” (2008-2012), finally plateauing around 78% by 2012. MIS, compared to laparotomy, had a significantly lower median estimated blood loss (125 mL versus 250 mL), lower rate of perioperative blood transfusions (0% versus 11%), shorter median length of hospital stay (one day versus five days). The total complication rate was significantly lower in the minimally invasive group (15% versus 36%), with notable decrease in wound complications (6% versus 27%). Robotic approaches, when compared to laparoscopy, had a less median estimated blood loss (50 mL versus 100 mL) and a lower median length of hospital stay (one day versus two days). The rate of conversion was higher in the laparoscopic group than the robotic one (12% versus 3%). The operative time and the rate of complications were similar between the two groups (robotic versus laparoscopy: 193 min versus 190 min; Table 9). A cost analysis found that laparotomy had the highest costs in the immediate perioperative period, up to 30 days postoperative, and up to 6 months postoperative. Of note, the operative time was longer in the MIS group when compared to laparotomy (191 minutes versus 170 minutes).

A retrospective study was conducted on 56 super morbidly obese women with endometrial cancer ($\text{BMI} \geq 50 \text{ kg/m}^2$) [158]. The goal was to study the feasibility, adequacy, and safety of robotic surgical staging in this subgroup of patients. A comparison between this subgroup and lower-weight patients found no differences in the yield of removed pelvic and para-aortic nodes. Blood loss, complication rate, recurrence, and survival were similar, but in patients with $\text{BMI} \geq 50 \text{ kg/m}^2$, there was a higher conversion rate (19.6% versus 8%).

These studies have shown the possible advantages of robotic surgery over laparoscopy in the subgroup of obese patients with endometrial cancer. It is important to note that all these studies were retrospective. Furthermore, obesity is a clinical situation that requires specialized and multidisciplinary approaches and a surgical plan that considers all aspects of the patient's health.

4.2. Elderly and Very Elderly Patients

More than 40% of patients with endometrial cancer are 65 years of age or older at the time of diagnosis, and among them more than 15% are older than 75 [162]. In this group of patients, the behavior of endometrial cancer has been described as more aggressive [163], and characterized by the presence of aggressive histological types, high histological grade and advanced stage [163]. However, these patients are more likely to have incomplete surgical

staging procedures or non-standard adjuvant treatments [164-167]. When compared to laparotomy, robotic surgery has shown a higher rate of comprehensive surgical staging, less blood loss, and a lower rate of perioperative complications both in the elderly (65 - 80 years old) and in the very elderly (≥ 80 years old) subgroups [167-172]. Despite these advantages, it must be acknowledged that elderly and very elderly patients have an intrinsic higher risk of surgical morbidity compared to younger patients [169, 173]. The balance of risks and benefits in this population remains undefined but robotic surgery is yielding promising results for a population that continues to rapidly increase.

4.3. Sentinel Lymph Node (SLN)

A significant current debate in the literature is the role of lymphadenectomy in endometrial cancer. Lymph node assessment is an important component of surgical staging in endometrial cancer for its diagnostic and prognostic functions and can help direct adjuvant therapies [70]. The debate is ongoing, due to the absence of proven survival benefit with lymphadenectomy for patients with early-stage endometrial cancer, with a significant increase in morbidity and costs [174-176].

SLN evaluation in endometrial cancer has a high rate of metastatic detection (86%) high sensitivity to detect node-positive disease (97% - 95% CI 85-100) and high negative predictive value (99.6% - 95% CI 97.9-100), as reported by the recent FIRES trial [177-181]. The NCCN has accepted SLN as an alternative to evaluate lymph node status and thus, many institutions (including Mayo Clinic) adopted SLN without proceeding to lymphadenectomy in patients for whom the SLN procedure is successful [69, 182-185].

In this evolving process, MIS play an essential role. MIS and SLN are a promising method to reduce morbidity, without compromising survival outcomes. The increasing expansion of each of these two procedures is lending a hand to the extension of the other [186, 187].

4.4. Other Gynecologic Cancers: Ovarian and Vulvar Cancer

Ovarian cancer (OC) is a relatively rare disease [188], but it represents the 5th leading cause of cancer death among women in the U.S. [64]. More than 60% of OC are diagnosed at an advanced stage [188], typically with diffuse intraperitoneal abdominal disease. An optimal debulking (no evidence of macroscopic disease at the conclusion of the surgery) is one of the leading prognostic factors [189, 190]. Due to ability to thoroughly explore the entire abdominal cavity, laparotomy is preferred to MIS in many institutions. Descriptions of robotic surgical approaches in OC are limited to case series [191-196], and the technique has been described as feasible in selected patients, such as those with early stage of disease or in selected cases of interval debulking surgery following neoadjuvant chemotherapy [191, 196]. Different robotic approaches have been described depending on disease location [191, 195, 197]. In this context, the higher maneuverability of da Vinci Xi may lead to future application of robotic surgery in OC.

Table 9. Complications and conversion rate comparison between robotic surgery and other surgical approaches in obese women.

						/	/	/	/

Vulvar cancers are rare tumors [198]. In these cases, a feasible robotic approach has been described for video-assisted inguinal lymphadenectomy [199], but is not yet accepted as a standard of practice.

4.5. Recurrent Gynecologic Cancers and Pelvic Exenteration

In patients with recurrent gynecologic neoplasms, the objective of any surgical procedures is to reach as complete a cytoreduction as possible while balancing perioperative morbidities. MIS, and specifically robotic surgery, may have a beneficial impact in this setting.

Robotic surgery has been described as a feasible approach for patients with localized recurrent OC without carcinomatosis [197, 200-202]. Its use has also been described in radical procedures such as pelvic exenteration for cervical and endometrial cancer recurrences [203-208]. In this aggressive procedure, the pelvic organs are completely resected with high rates of perioperative morbidity and mortality [209, 210]. Although case reports and case series have suggested a robotic approach is a feasible option in terms of perioperative and pathologic outcomes [203-208], a comparison of surgical and oncologic outcomes among different surgical techniques is still lacking.

5. DESCRIPTION OF SURGICAL TECHNIQUES

5.1. Total Hysterectomy

A total hysterectomy with bilateral salpingo-oophorectomy is indicated as part of surgical staging for patients with a diagnosis of endometrial cancer. The surgical technique performed at the Mayo Clinic for these cases is described below. At Mayo Clinic, endometrial cancer is the primary gynecologic oncology indication for robotic surgery.

After positioning the patient in a lithotomy position, the stomach is deflated with an orogastric tube, which is left in place throughout the entire operation. Our preferred technique for the creation of the pneumoperitoneum is open laparoscopy (dissection through the umbilicus and peritoneal entry under direct vision). An alternative approach is the insertion of a Verres needle through an umbilical incision. Pneumoperitoneum to 15 mm Hg is then created.

After insertion of the first trocar and the camera port (at the level of the umbilicus, or three to five centimeters above it depending on patient habitus and uterine pathology), a total number of three 8-mm ancillary robotic trocars are inserted under direct visualization (Figure 6). One ancillary trocar is usually added to allow the surgical assistant to access to the pelvis with laparoscopic instruments (vessel sealer devices, graspers, bowel retractor, suction irrigator), and to pass sutures to the surgeon (Figure 6).

After trocars are safely inserted, a meticulous inspection of the abdominal cavity is accomplished and every suspicious lesion is biopsied.

In a low lithotomy position with legs padded in Yellofin stirrups, the patient is gently tilted into full Trendelenburg. It should be remembered that maintaining a patient in steep

Trendelenburg for more than three hours may predispose to brachial plexus injury, corneal abrasions, posterior ischemic optic neuropathy, laryngeal edema and cerebral edema [211]. However, these complications are possible but rare.

Appropriate instrumentation is crucial to completing a successful robotic procedure. A bipolar grasper is usually placed in the non-dominant robotic hand, in order to facilitate grasping, coagulating and sealing vessels throughout the procedure. In the dominant hand port, a unipolar spatula, monopolar shears (scissors), are typically placed to facilitate dissection. ProGrasp forceps (atraumatic graspers) are typically inserted into the additional port to facilitate dissection.

Figure 6. Trocar position with da Vinci Si located caudal to the abdomen and to the patient's left side. It should be noted that, with the da Vinci Xi, it is possible to position all the robotic trocars on a horizontal line at the level of the umbilicus, while the robot is positioned on the left side of the patient, at our institution. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

Different surgeons tend to prefer different instruments. The disadvantage of a unipolar spatula is that it does not allow spreading of tips and tissue separation for plane identification. In our opinion, monopolar scissors are better instruments to achieve these surgical movements. In difficult cases (elevated BMI or challenging anatomy), the Ligasure (Medtronic, Minneapolis, MN) is utilized for sealing and transecting large vessels. The Ligasure is an instrument which combines both pressure and energy to create vessel fusion and has been associated with decreased blood loss and operative time [212, 213].

With the aid of a uterine manipulator or the ProGrasp da Vinci retractor, the uterus is elevated off the pelvic floor, and the surgeon begins on one side of the pelvis. At Mayo Clinic, the uterine manipulator is not used routinely. Instead, a blunt probe (apple probe) (Apple Medical, Marlborough, MA) or vaginal dilator) is used to elevate the uterus and demarcate the vaginal fornices. This probe proves useful especially at the time of development of the vesicovaginal space and for the anterior and posterior colpotomy.

The hysterectomy is started by grasping the uterine cornua with the ProGrasp, elevating and laterally displacing it to put the tissues on tension. The round ligament is cauterized and

cut, the posterior leaf of the broad ligament is opened with a monopolar instrument, and the retroperitoneum is exposed. Carbon dioxide from the pneumoperitoneum enters the retroperitoneum and assists in facilitating dissection. The incision on the posterior leaf of the broad ligament is extended to the pelvic brim to facilitate identification of the ureter and the iliac vessels.

The ureter can be identified transperitoneally (usually near the pelvic brim, just medial of the infundibulopelvic ligament), or retro-peritoneally. Our recommendation is to identify the ureter retro-peritoneally during this initial dissection. This step typically requires minimal time and allows adequate lateral mobilization of the ureter. It aids in procedural safety by allowing easier identification of pelvic anatomy.

After the identification of the ureter, the external iliac vessels and infundibulopelvic ligament may be identified. A peritoneal window below the ovarian ligament is created, and the ovarian vessels are divided using bipolar current either from a robotic instrument or a vessel sealer.

The third robotic arm (typically the ProGrasp) then moves to grasp the bladder peritoneum and the uterus is allowed to relax posteriorly. The anterior leaf of the broad ligament is incised toward the direction of the bladder. The peritoneum is incised superficially; avascular areolar tissue is exposed and dissected. This continues as the bladder is identified and mobilized anteriorly with the uterus positioned posteriorly. The apple probe proves useful to place the anterior vagina on tension and identify the vesico-vaginal plane. When this plane is obscured (such as in patients who have had Cesarean deliveries), it may be useful to fill the bladder with saline or other sterile solution to assist in identification.

At this point, the uterine vessels can be identified and skeletonized. The medial leaf of the posterior peritoneum is incised at the level of the uterosacral ligament to allow the ureter to displace slightly posterior and lateral. This also thins the tissue at the level of anticipated colpotomy. The third robotic arm may be used to provide counter-traction on the uterus to expose the cardinal ligament. In selected cases, coagulation of the uterine artery with the Ligasure may increase efficiency of this step. The vascular stump is then gently mobilized laterally. During this mobilization, medial coagulation with the bipolar instrument is usually required. The same procedure is then performed on the contralateral side.

The development of the vesicouterine or vesicovaginal reflection can now be continued. The previously incised bladder peritoneum is grasped by the third robotic arm to provide counter-traction while dissecting the bladder away from the para-cervical fascia. During this step, an assistant positioned between the patient's legs must apply pressure to the apple probe against the cervix to displace it away from the bladder.

Colpotomy is performed using monopolar cauterization. The ascending vaginal branches are cauterized bilaterally to ensure hemostasis at the vaginal corners and the vagina is circumferentially incised. The vagina is placed on tension by the apple probe. The incision is usually started in the anterior midline until a full thickness vaginal incision is made and the apple probe visualized. The colpotomy is continued laterally along vagina (as a "frown shaped" incision). Then the cervix is grasped and the posterior colpotomy is completed. It is essential to use all robotic and assistant arms to optimize visualization during this circumferential incision to avoid that incidental or unplanned injury occurs to the adjacent structures.

In obese patients, the posterior colpotomy is better performed separately. The posterior vagina is placed on tension with the apple probe and the colpotomy is performed starting at

the posterior midline, then continuing laterally (with a “smiling shape”). The uterus is delivered through the vagina after being grasped with a ring forceps by the assistant located between the patient’s legs. Once the uterus is extracted, the vaginal cuff closure is performed robotically. Our preference is to start at the right lateral corner. A running submucosal closure is performed and allows appropriate approximation and eversion of the vaginal mucosal edges. This is believed to minimize the risk of vaginal cuff dehiscence. The second layer of vaginal cuff closure is performed as a running suture with the goal to imbricate the edges of the first layer. The use of the third arm can be useful to maintain counter-traction and elevate the vaginal cuff to facilitate the closure. Before completing the operation, hemostasis is accurately checked.

5.2. Radical Hysterectomy

Radical hysterectomy (type C according to Querleu & Morrow classification system [67, 107] – Table 6) is the most frequent type of surgical procedure for cervical cancer. The majority of these procedures are now being completed through a minimally invasive modality, attributable to the adoption of robotic surgery [119, 214].

Historically, RH is related to a high prevalence of bladder and rectal dysfunctions [215]. A nerve-sparing RH [216] has been described to decrease these dysfunctions [214, 216-218], without jeopardizing oncologic outcomes [219] and can be performed robotically.

Figure 7. Splanchnic nerves, superior and inferior hypogastric plexus [220]. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

Nerve-sparing RH is defined by preservation of the hypogastric plexus (superior and inferior) and splanchnic nerves (including sympathetic and parasympathetic fibers as well as visceral afferent sensory fibers (Figure 7 and 8). The procedure has been very well described by Dr. Magrina from Mayo Clinic Scottsdale [220]. We learned from him and we follow his technique in our group at Mayo Clinic Rochester. We will describe it here accordingly.

The 3D vision, amplification and tremor control provided by the robot allows visualization and precision during radical dissection.

When completing a RH, the para-vesical and para-rectal spaces are thoroughly dissected and prepared. The intersection of the uterine artery and the ureter, the uterine vein, and the deep uterine vein are identified. The parametrium and the parametrial vessels (including the superior vesical and uterine arteries) are transected with the Ligasure at their origin from the hypogastric artery and vein to the level of the deep uterine vein. In the posterior pararectal space below the deep uterine vein, the “neural portion” of the parametrium can be identified containing the pelvic splanchnic nerves (Figure 8) [221]. In the type C1 (nerve sparing) RH this portion is preserved, while in a type C2 (non-nerve sparing) RH this part is not preserved [107].

Figure 8. Preservation of the splanchnic nerves during the parametrial resection of a nerve-sparing RH (type C1) versus a conventional RH (type C2) [220]. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

The inferior hypogastric plexus (IHP - union of the superior hypogastric plexus with the pelvic splanchnic nerves) may be identified by mobilizing the caudal edge of the transected parametrium cranially [107, 222]. A monopolar spatula is used to horizontally incise the

peritoneum of the cul-de-sac in order to open the rectovaginal space. Blunt dissection of this space is then performed. Both the uterosacral ligaments must be identified. The ventral mobilization of the uterus with the ProGrasp can assist in this process. The IHP is located in the lateral portion of the uterosacral ligaments. It may be helpful to consider the uterosacral ligaments as being composed of a lateral “neural” portion and a medial “ligamentous” portion [220, 223]. A monopolar spatula is used to divide these two portions of the uterosacral ligaments selectively, mobilizing and preserving the IHP. After this dissection, the medial uterosacral ligaments are transected at the level of the anterior rectal wall. Preservation of the hypogastric plexus is the key to the type C1 RH, while in type C2 this plexus is transected.

Attention is then turned to the anterior compartments. The ureter must be identified at its entrance into the parametrial tunnel. The tunnel must be widened until a surgical instrument can be inserted and the ureter unroofed. After opening the ventral portion of the vesico-uterine ligament, the ureter must be retracted laterally and the anterior vesico-uterine ligament dissected. The IHP is identified below the dorsal border of the parametrium. The IHP must be mobilized dorsally and laterally. Now, the posterior vesico-uterine ligament must be identified and isolated, using the avascular space below the ureter entry into the bladder (Figure 9). During the transection of the posterior vesico-uterine ligament, the dorsal portion of this ligament (near to the inferior vesical artery) must be preserved. In this portion, the IHP fibers, entering the bladder and the vagina, can be identified [220, 224]. The transection of the posterior vesico-uterine ligament at this point must be performed in close proximity to the ureter. The dissection of the paravaginal tissues with the monopolar spatula is then performed. The IHP fibers are located near the lateral side of the vaginal wall. To prevent the transection of these fibers during the vaginal transection, the IHP can be mobilized, along the lateral portion of the vagina, below the level of transection.

Figure 9. Fibers of the IHP run along the dorsal vesico-uterine ligament [220]. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

5.3. Lymph Node Assessment

The boundaries for a systematic pelvic lymphadenectomy are: superiorly the common iliac artery; inferiorly the circumflex iliac vein; laterally the pelvic sidewall and the mid psoas muscle; medially the hypogastric artery and the obliterated umbilical artery (its terminal branch) and dorsally the obturator nerve and obturator fossa.

The boundaries for the para-aortic lymphadenectomy are the following (from right to left side): the right psoas muscle, the right ureter (medial to the psoas muscle and lateral to the inferior vena cava, crossing the bifurcation of the common iliac artery), the vena cava (lateral to the aorta), the aorta and the common iliac arteries, the superior hypogastric plexus (superficially, below the bifurcation), the left common iliac vein, the right and left renal arteries and the left renal vein, the left ureter, the sigmoid colon, the lumbar vessels (artery and vein) and the left psoas muscle.

During the lymph node dissection, particular attention must be paid to possible anatomic variants (vascular, neurologic, and urologic). Sympathetic and parasympathetic nerves (sympathetic chain, post-ganglionic sympathetic fibers, and hypogastric plexus) can be preserved to avoid organs dysfunctions related to the procedure (i.e., nerve-sparing procedure) [225] (Figure 10).

Figure 10. Superior hypogastric plexus and its branching in front of the sacral promontory (Open abdominal view). Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

5.3.1. Sentinel Lymph Node Biopsy

As previously described, our group does not recommend full lymphadenectomy for patients in which SLN sampling procedure is successful.

Different tracers, injection techniques and sites of injection into the cervix have been described [226, 227]. At Mayo Clinic, the patient is positioned into low lithotomy and stirrups are used for leg repositioning to facilitate an adequate visualization of the cervix for the injection of the tracer. Four milliliters of Indocyanine Green (ICG) are injected into the cervix at 3 and 9 o'clock. In each site, a superficial injection (1-3 mm) is performed. The purpose is to deliver the dye in the layer of the cervix from which most of lymphatic channels originate. Typically, a lymphatic channel draining from the cervix crosses the obliterated umbilical artery to the most common sentinel nodes localizations: the external iliac artery or the superior part of the obturator fossa. A less frequent localization includes the iliac pre-sacral region, at the level of the iliac bifurcation (Figure 11).

A near-infrared camera is required to localize the sentinel node when ICG is selected as the tracer. For a correct identification of the primary drainage node of the uterine body, it is crucial to open the avascular surgical spaces appropriately. The para-vesical space must always be opened to identify a possible sentinel node in the obturator fossa. Also, constant knowledge of the ureter's location is critical to avoid injury.

Figure 11. Lymphatic drainage of the uterine body. Two main lymphatic paths: one that drains mainly into the medial external iliac artery or in the superior part of the obturator fossa; the second one drains into the iliac pre-sacral region, following the mesoreuter. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

5.3.2. Pelvic Lymphadenectomy

The identification of anatomic landmarks (such as the umbilical artery, ureter and external iliac vessels) is of paramount importance in robotic pelvic lymphadenectomy.

The peritoneum is opened at the level of the round ligament. For this description, we will assume that the retroperitoneum has been already opened and the ureter identified, as described in the hysterectomy portion of this chapter. Before starting the lymphadenectomy, the para-vesical space must be opened. It is lateral to the obliterated umbilical artery and medial to the external iliac vessels. In the very obese patients, in whom the external iliac vessels are not easily identified, it is important to start the dissection laterally, above the iliopsoas muscle, and gradually move medially, until the external iliac vessels are identified.

5.3.2.1. External Iliac and Common Lymph Nodes

The dissection starts caudally, on the anterior surface of the external iliac vessels with the most anterior landmark being the circumflex iliac vein [228]. The genito-femoral nerve on the ventral aspect of the psoas muscle is followed along its course and is detached from the surrounding lymph nodes. The cranial end of the lymphatic tissue is divided using bipolar electrocautery at the level of the common iliac vessels. Reaching the common iliac vessels may require appropriate retraction of the bowel and the ureter in obese patients. The lymph nodes are then grasped and retracted in a medial direction to allow gentle blunt and sharp dissection of the underlying vein.

5.3.2.2. Obturator Lymph Nodes

At this point, the external iliac vessels are gently mobilized medially, separating them from the lateral muscular tissue. Remaining lateral to the vessels, the deep obturator lymphatic tissue is mobilized medially from the pelvic sidewall. This step facilitates subsequent complete dissection of the deep pelvic lymph nodes. The dissection then continues medially at the level of the obturator and internal iliac arteries. During this step, the obturator nerve is visualized and bluntly freed from the surrounding lymphatic tissue thus allowing entry into the obturator fossa. Particular attention must be paid not to injure the accessory obturator vein, which may bleed if damaged. If appropriate, to facilitate this part of the dissection, this vein may be clipped and cut. The dissection then continues cephalad, until the deep nodes are encountered at the level of the iliac bifurcation. The lumbosacral trunk should be visualized deep posterior and laterally in order to safely perform a full dissection.

5.3.2.3. Internal Iliac Lymph Nodes

The lymph node bundle is retracted medially, and the internal iliac vessels are denuded from the lymphatic tissue. The lymph node bundle is usually removed en-bloc. To obtain an adequate staging, the external and internal iliac arteries, the bifurcation of the common iliac artery, and the obturator nerve should be all visible at the end of the procedure.

5.3.3. Para-Aortic Lymphadenectomy

The feasibility of a complete robotic para-aortic staging up to the level of the left renal vein may be challenging, especially in severely obese women [229].

Before starting the dissection, the peritoneum is first opened at the mid-portion of the right common iliac artery, and then the incision is extended up to the aortic bifurcation to open the retroperitoneum and to expose the surgical field. The peritoneal edges are kept on tension by the third robotic arm, by the assistant, or by straight needles creating a “peritoneal tent.” It is prudent to mobilize the bowel far from the operative field. A laparoscopic fan retractor can serve this purpose well. Similarly, the omentum or 1-2 sponges can be used to

manipulate the bowel and help keep the operative field visible. In obese patients, the epiploic tags of the sigmoid may be sutured against the left abdominal wall to hold the bowel outside of the operative field. The visualization and dissection of para-aortic lymph nodes above the inferior mesentery artery (IMA) (especially on the left side) may be limited in obese patients. An advantage of the da Vinci Xi robot allows visualization and assessment of the upper para-aortic area without repositioning the robot (which is sometimes necessary with the da Vinci Si) [230]. The positioning of the camera trocar above the umbilicus (more cranial than the other ports) at the beginning of the procedure may facilitate the visualization of the upper para-aortic area. The positioning of the third arm on the right side of the patient will help facilitate tissue retraction and exposure. The right ureter, the common iliac vessels, the aorta and vena cava must be clearly identified before starting the dissection.

5.3.3.1. Right Para-Aortic Lymph Nodes

The first lymph nodes to be dissected are on the right side of the right common iliac artery and then on the right and anterior portion of the aorta. In fact, the large arteries are less likely to bleed than the veins, and the vessels in this area only rarely present significant anatomical variation. The dissection continues with the removal of the inter-aortic nodes, followed by the lymph nodes anterior and lateral to the vena cava. The dissection is extended cranially until the entrance of the renal vein into the vena cava.

5.3.3.2. Left Para-Aortic Lymph Nodes

A supplementary extension of the peritoneal incision is performed to obtain optimal exposure of the left aortic lymph nodes. The left ureter is identified as well. After gentle retraction of the sigmoid mesentery by the assistant, the infra-mesenteric nodes can be removed from the bifurcation of the aorta to the level of the IMA with meticulous blunt and sharp dissection. The third robotic arm or a fan retractor is usually helpful in exposing the lower left para-aortic area.

Exposure of the infra-renal left lymph node packet can be obtained by either preserving or dividing the IMA at its origin from the aorta with a vessel-sealing device. The division of the IMA is usually safe in patients who are not elderly and/or with major vascular disease [169]. The lymph nodes can be removed from the IMA to the left renal vein and medial to the left ovarian vein. During the entire procedure, particular attention should be paid to avoid injury to the lumbar vessels, the left common iliac vein, and the left ureter.

CONCLUSION

- The utilization of minimally invasive surgery in the field of gynecologic oncology has increased during the last decade, mainly due to the advent and implementation of robotic surgery.
- Advantages of robotic surgery include: a fast learning curve to gaining surgical proficiency and efficiency, feasibility and safety in the obese and morbidly obese populations, and facilitation of novel procedures such as sentinel lymph node mapping and biopsy.

- The primary disadvantage is the cost of the modality itself. However, it has been demonstrated that an increase in the volume of the procedures performed on one robotic system can balance the initial purchasing expenses.
- Current indications for robotic surgery in gynecologic oncology are endometrial and cervical cancer staging. The utilization of the technique in ovarian and vulvar cancer is under investigation.

INTRODUCTION

Since the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) was approved by the Food and Drug Administration in December 2009 for the management of T1 to T2 head and neck cancers, transoral robotic surgery (TORS) has rapidly spread throughout the United States, with a sudden shift from primary chemoradiation therapy (CRT) for early oropharyngeal cancers toward first-line TORS. Currently, TORS is used mostly for the resection of oropharyngeal as well as select hypopharyngeal and supraglottic tumors.

There are three main reasons for this quick shift from CRT to first-line TORS for early oropharyngeal cancers [1]:

First, and most importantly, the widespread use of CRT resulted in significant acute and chronic morbidity, and the skepticism has been mounting as to the net benefit of first-line CRT in terms of overall survival (OS) and quality of life (QOL) in comparison to first-line definitive surgery for early stage oropharyngeal squamous cell carcinoma (SCC). The introduction of a surgical modality with lower morbidity than traditional open approaches has provided the impetus toward reconsidering treatment paradigms [2]. Also, the demographics of oropharyngeal cancer have been changing, from older patients with chronic tobacco and alcohol abuse and multiple comorbidities, to younger, otherwise healthy, patients with human papillomavirus (HPV)-associated oropharyngeal SCC [3-6]. This has made the concerns surrounding the benefits of first-line CRT use more prominent since the long term morbidity

of radiation therapy can be more significant in younger patients [7]. The long-term effects of primary CRT versus first-line surgery on QOL and OS must be carefully considered in this new patient demographic [8, 9].

Second, the increasingly dominant use of first-line CRT over the past several decades led to new generation of head and neck surgeons with less experience in performing open procedures for early stage oropharyngeal SCC, so they were open for a new surgical modality that may reduce the treatment-related morbidity for the younger, healthier HPV-positive patient population.

Third, the safety and oncologic data resulting from other minimally invasive surgical modality, such as transoral laser microsurgery (TLM), provided a solid ground on which a novel minimally invasive technique could take hold [2]. Not surprising that the increasingly younger patient demographic with HPV-positive oropharyngeal SCC, combined with the novel minimally invasive approach offered by TORS is tipping the scale back toward definitive surgery.

Beside the aforementioned reasons for the wide use of TORS in the United States, the TORS approach features several important advantages over traditional and other minimally invasive surgical approaches. TORS has been shown to be an effective surgical alternative for open surgeries as it can achieve negative margins while avoiding some of the morbidity and disfigurement from external approaches [10]. In general, benefits of TORS include three dimensional magnified, and ‘around the corner’ views, the ‘wristed’ instruments allowing for translation of intuitive hand movements into small, finely controlled movements of the instruments and negation of tremor. Specific to the head and neck, TORS allows the surgeon to view and dissect technically difficult anatomical areas, without the need for external incisions and without compromising local control or survival [11, 12]. For patients, the TORS procedure has been shown to improve functional outcomes in speech and swallowing while maintaining good oncologic outcomes compared to open procedures [13]. The TORS approach also has a short learning curve [14], which makes it appealing to new surgeons. After an initial learning phase, the operating time including robot setup time was comparable to traditional endoscopic surgery.

INDICATIONS AND PATIENT SELECTION

McLeod and Melder performed the first application of the da Vinci surgical robot for endolaryngeal surgery in 2002 to resect a vallecular cyst [15]. The case was a proof of concept, opening up the use of the robot in the field of head and neck surgery. Subsequently, extensive research on application of the da Vinci surgical robot in performing endoscopic surgery in the oropharynx, larynx, and hypopharynx was performed by the University of Pennsylvania group. The study started on an airway mannequin [16], progressing to cadaveric dissections [17-19], and later to a canine model [20, 21]. After the success in the preclinical phase of the study, the group embarked on Phase I clinical trials in 2006 with case series on resection of base of tongue cancers [17], tonsillar cancers [22], and supraglottic cancers [23]. The FDA approved the use of the da Vinci surgical robot for endoscopic resection of early T-stage (T1–T2) head and neck cancers in 2009. The operation was subsequently named “transoral robotic surgery” (TORS). Other centers expanded TORS for resection of early

cancers in the hypopharynx, larynx, and nasopharynx [24]. After adoption of its use in early upper aerodigestive tract cancers, several centers subsequently confirmed the technical feasibility, safety, oncologic outcomes, and functional improvements that TORS resection is capable of [22, 25-27]. As of 2014, TORS is approved by the FDA for the resection of benign and cancerous tumors of the oropharynx classified as T1 and T2 and for benign tongue base resection procedures. It also has increasing use in resecting cancers in the larynx and hypopharynx, and tumors in the skull base, as showed in table 1. TORS for benign conditions, especially tongue base resection for obstructive sleep apnea, has been increasingly investigated.

Given the properties of TORS, the ideal TORS candidates will include the following characteristics [1]:

1. No general contraindications to surgery
2. Primary tumor is functionally well resectable, without significant long-term impairment
3. No radiologic sign of extracapsular extension (ECE) of the draining lymph nodes
4. Clear surgical margins likely to be achieved for the primary tumor,(ideally 5 mm)
5. Surgery is likely to result in the reduction or elimination of adjuvant CRT.

Hans et al. identified contraindications of TORS [28], including patients with contraindications to general anesthesia, unresectable tumors (related to size or location of the tumor), invasion of tumor into the mandible, advanced tongue base tumors requiring >50% resection of the tongue, advanced pharyngeal tumors requiring >50% resection of the posterior wall, and vertebral involvement. The current technology limits transoral access to the larynx and hypopharynx in patients with poor neck extension or anterior larynx exposures. In addition, patients with anatomic restrictions such as trismus can make adequate exposure impossible. As technology improves with smaller instruments and single port docking, surgical access to patients with unfavorable anatomy will broaden indications for the transoral approach.

Table 1. List of transoral robotic procedures currently performed or investigated, excluding cadaveric experiments

Robotic radical tonsillectomy
Robotic tongue base resection
Robotic supraglottic laryngectomy
Robotic partial laryngectomy
Robotic hypopharyngectomy
Robotic total laryngectomy
Robotic-assisted transoral laser excision (oropharynx, larynx, and hypopharynx)
Robotic-assisted inseting of flaps
Robotic microvascular anastomosis for free flaps
Robotic lingual tonsillectomy for sleep apnea
Robotic resection of parapharyngeal tumors
Robotic nasopharyngectomy

DISADVANTAGES OF TORS

The da Vinci surgical robot was not originally designed to be deployed in the head and neck region, which can result in arm collisions in small working space. It is still too bulky to use in places like the anterior skull base. A new surgical robot (model: da Vinci Xi) with a smaller footprint and less chance of arms collision has already been launched in the market, but, unfortunately, it has not been specifically designed for transoral use and FDA approval for TORS has not been sought. Competing robotic systems and single port platforms are being designed and investigated [29, 30].

Lack of tactile feedback is another criticism of robotic surgery and this is also true for TORS. Robotic surgeons currently substitute the tactile sensation mainly with visual cues to a certain extent, but visual cues could not entirely replace tactile sensation. VerroTouch (U. of Pennsylvania Haptics Group, Philadelphia USA) is an early attempt to produce an external add-on to the da Vinci surgical robot to provide haptic feedback to the operating surgeon [31, 32]. A small-scale survey of the advantage of the VerroTouch system has been completed by eleven robotic surgeons and the majority welcomed the addition of the haptic feedback, but none found it essential.

Currently, TORS mainly uses monopolar and bipolar cautery for hemostasis. They tend to work inefficiently in deep dissection due to difficult visualization and too much debris from the cautery. An ultrasonic dissector would be a better instrument for dissection around areas prone to bleeding like venous plexus in the pterygoid plexus and parapharyngeal space, but the current robotic ultrasonic dissector is too bulky and lacks articulation. So, the development of alternative energy-source instruments for hemostasis and dissection and their integration with robotic instruments will be a welcomed innovation.

The other disadvantage of robotic procedures is the high cost. The cost of the robot, disposable and nondisposable robotic instruments, dedicated and delicate micro-instrumentation, and robot-specific supplies all are expensive [33, 34]. This is however been an area of study which has demonstrated a comparable cost effectiveness to chemoradiation with possible reduced overall treatment-related costs owing to reduced late gastrostomy and tracheostomy tube dependence.

Also, the surgical procedure is technically challenging and necessitates the training of all levels of surgical personnel. Due to its special configuration and different room setting, to prevent injury while operating the robot during the TORS procedure, the surgical team must remain aware of the patient risks. Potential patient injuries include lip and dental injury, mucosal injury, facial lacerations, mandible fracture caused by rotation of robotic instrument, cervical spine injury caused by robotic instrument torque, ocular injury, and post-operative airway edema [33, 34].

PRACTICAL SET UP AND SAFETY CONSIDERATIONS OF TORS SURGERY

When it comes to the practical set up of TORS surgery, it should be emphasized here that, while many operating rooms have personnel trained in the use of the da Vinci® Robotic

System for other specialties, appropriate TORS specific training is necessary for all members of the team who will participate in the planning and execution of TORS procedures.

The size of the operating room used for TORS procedures should be large enough to accommodate the considerable amount of equipment required. The night before surgery the team assigned to the case should review the TORS procedure manual and the physician's preference card.

Primary equipment required for TORS:

1. da Vinci® Robot (which consists of patient-side cart, surgeon consoles, and vision cart)
2. Laryngoscopy and airway carts
3. Secondary video tower
4. Procedural case cart (contains all the needed instrumentation)
5. Surgical high-magnification camera head (0 and 30 degree angled view)
6. High-definition 3D imaging system
7. Robotic instruments (selected by surgeon in advance)
 - a. Maryland dissecting forceps
 - b. spatula tip monopolar cautery
8. Cautery unit with Bovie pedal and bipolar pedal (for assistant at bedside), two Bovie pads, and reusable bipolar cord.
9. Oral retractors such as Crow-Davis or FK retractors

Other equipment and instrumentation required for TORS include patient's surgical bed with gel pads and mattress and warming blanket, three sterile surgical tables, two Mayo stands, sequential compression device, chairs with height adjustment capability - two at bedside (for the nurse and the bedside surgical assistant), one for the teaching console (if applicable), and one at surgeon console, and three rectangular OR instrument carts and one small square OR instrument cart. Other routine surgical instruments, in addition to the da Vinci® Robotic System and its components, are used by the surgical assistant at the bedside should include surgical headlight, lip and tongue retractors, needle holders, debakey forceps, metzenbaum or tonsil scissors, hemostats, suction cautery, Yankauer suction, small and medium vascular clips.

The universal protocol is performed and general endotracheal anesthesia is induced after the patient enters the room. A single lumen reinforced tube should be used, and can be an oral or nasal intubation depending on surgeon preference. In either case, the endotracheal tube is placed in the side contralateral to the tumor. The bed is turned 180° with the patient's feet towards anesthesia. An extended breathing circuit is used to reach the endotracheal tube (Figure 1). Both of the patient's arms are wrapped in gel arm wraps and tucked. The patient's head is placed on a low profile "gel donut." The assistant to the surgeon positioned at the patient's head attends to the surgical site with handheld instruments. The assistant observes the surgical site directly and on one of the video monitors and performs tasks such as suctioning, cautery, applying vascular clips, and ensuring that robotic arms do not cause injury to patient.

Afterwards, the patient-side cart is moved to the edge of the patient bed and aligned at a 30° angle from the long axis of the patient surgical bed. A mouth gag and retractor, depending on the type of procedure and patient anatomy, are placed for TORS procedure with

good oropharynx and the lesion exposure. The surgeon should place the desired mouth gag before final positioning of the patient-side cart. Once the mouth gag is placed, it should be suspended using a low profile suspension device to avoid interference from the robotic arms. The suspension device should be fixed to the patient surgical bed on the side opposite the patient-side cart. After the mouth gag is in place, the robotic arms are moved and positioned over the patient's chest. The trocars are then placed in the trocar holders, and camera-endoscope arm is positioned with trocar in the center of the patient's mouth. The right and left instrument arms are placed just inside the corners of the mouth taking care not to put pressure on the lips or teeth (Figure 2).

Figure 1. Operating room set up for da Vinci TORS.

Figure 2. Position of the cannula, camera and instrument arms relative to the mouth gag and oral cavity.

Special considerations:

1. Airway fire:

The risk of fire is present when a laser is to be used during TORS or even when use the cautery arm of the da Vinci® Robot. The first steps when a fire is noted are to turn off the oxygen and remove the endotracheal tube. The mouth gag or retractor may need to be released first before the endotracheal tube can be removed completely. There should be 1 L of saline in an open container available to be poured in the mouth. If the fire is extinguished, ventilation should be reestablished. The endotracheal tube should be inspected for missing parts that may be still be in the airway. A bronchoscopy can be performed to evaluate the airway for remaining foreign bodies and retrieve them if present [35].

2. Eye protection:

“Optigard eye protection” (Dupaco Inc, USA) or a similar rigid eye protection should be used for all TORS procedures. They are adhesive backed, foam goggles with hard plastic lenses that are placed over the patient’s eyes to protect them from any possible pressure from any of the robotic or surgical instruments (Figure 2).

3. Lip/mouth injury:

A white latex free silicone tooth guard is placed over the teeth to provide a level of protection. A clear plastic “lip retractor” should be used to protect the lips from injury by the instrument arms of the robot. This can be placed before or after placement of the mouth gag.

POSTOPERATIVE CARE

The recovery course will depend on the extent of the surgery and how good the patient’s general health condition. In our practice, if patients have extensive TORS oropharyngeal resection, they are often kept intubated overnight for potential postoperative hemorrhage and airway obstruction. For this reason, IV corticosteroids are routinely given perioperatively for 24 hours. Otherwise, most patients with limited resections can extubated and transferred to an ICU or step-down unit. Depending on the extent of the surgery, a nasogastric feeding tube may be needed, and can be removed once the patients starts oral liquids. Typically, oral feeding is started on the first postoperative day in conjunction with a speech pathologist. Pain management should be adequate for quick recovery of dysphagia.

As with any procedure, there are risks we should be aware of. The exact risk will vary depending on the extent and type of TORS, and including surgical site bleeding, dysarthria, dysphagia, and even salivary fistula. With staged neck dissection and TORS, the chances of this decrease. When patients have dysarthria or dysphagia, speech therapy should be consulted, and pain control should be adequate.

STEPS OF TORS RADICAL TONSILLECTOMY

Differently from plain tonsillectomy in which dissection is carried through the peritonsillar space to excise the contents of the tonsillar fossa (i.e., the tonsil), radical tonsillectomy includes the resection of the walls of the tonsillar fossa. Dissection is done laterally to the constrictor muscle, into the parapharyngeal space, which provides the surgical margin required for oncologic safety. Weinstein et al. described TORS radical tonsillectomy [36] based on a previous transoral nonrobotic radical tonsillectomy (lateral oropharyngectomy) technique [37]. TORS provides an unparalleled vision and dexterity offered by the robotic instrumentation that allows the procedure to be highly effective and reproducible [38].

Figure 3. Steps in radical tonsillectomy.

Step 1. Initial incision to mark the superior and lateral superficial limits (dashed line). The incision is made with the monopolar cautery in a question-mark fashion to extend into

the pterygomandibular raphe. The dotted line shows the inferior and medial superficial limits that will be marked later.

Step 2. Deep dissection starts after transecting the superior constrictor muscle. The parapharyngeal fat pad is reached and bluntly dissected laterally.

Step 3. An index cut in the posterior pharyngeal mucosa marks the superficial medial limit.

Step 4. The superior limit is completed with full width transection of the tonsillar pillars.

Step 5. Inferior superficial limit in the tongue base.

Steps 6 and 7. Completion of the lateral limit by transection of the styloglossus (step 6) and stylopharyngeus muscles and the rest of connective tissue attachments (step 7).

Step 8. Completion of the inferior limit (deep tongue base).

Step 9. Completion of the deep medial limit (superior constrictor muscle) approaching either medially, laterally, superiorly, or inferiorly depending on the exposure.

Specimen is then completely free and can be taken out of the surgical field by the assistant. A couple of sutures can be done from the remaining posterior pharyngeal wall to the soft palate, to help nasopharyngeal closure when swallowing. The rest of the wound is left open; a hemostatic agent can be applied topically. No reconstruction is required. Intraoperative margins should be free of disease by frozen sections.

TORS IN UNKNOWN PRIMARY CANCERS

A common presentation for HPV related oropharynx cancer is a patient with a neck mass from metastatic squamous cell carcinoma with an unknown location of the primary tumor. Positive HPV testing on a fine-needle aspiration of the neck mass correlates with an oropharyngeal primary tumor location, especially in the context of a young non-smoker patient. The primary lesion is often small or hidden from view in the depths of the lymphoid tissue crypts, making identification difficult even with a thorough exam and endoscopy. Patients present with an unknown primary head and neck malignancy in 2-5% of cases, and traditional localization methods of PET-CT and direct laryngoscopy with tonsillectomy and biopsies fails to localize the tumor in 50-70% of patients [39]. This can be due to small primary tumors which are difficult to visualize or palpate due to their location in the crypts of the tonsil and tongue base lymphoid tissue.

Without identification of the primary tumor, a wide treatment field of high dose radiation to incorporate both palatine and lingual tonsils is undertaken to cover likely locations of the unfound primary tumor. This treatment leads to increased morbidity compared to the limited surgical resection or targeted Intensity-Modulated Radiotherapy that can be applied when the tumor location is identified. In addition to reduced treatment toxicity, localization of the primary tumor increases survival rates and local control.

The improved magnified visualization and oropharyngeal access of TORS and transoral laser microsurgery has allowed for a new approach to localizing head and neck cancers of unknown primary. After failure to identify the primary tumor with rigid endoscopy, one commonly adopted protocol is to perform an ipsilateral palatine tonsillectomy and lingual tonsillectomy to be evaluated for frozen section. If the site is still not found, the contralateral lingual tonsillectomy is performed. When the primary site is located, immediate oncologic

resection with frozen section evaluation of margins is performed using the TORS technique [40, 41]. This approach led to identification and resection of the primary tumor in 80-89% of unknown primary tumors, which lead to reduced treatment toxicities and improved quality of life [41-43].

The TORS approach to lingual tonsillectomy has been a useful tool in many centers for localizing unknown primary cancers. Localization has allowed for reduced treatment morbidity by reducing the size of the required radiation fields and allowing for de-intensification of the treatment dose if negative margins are obtained. The ultimate goal of these treatment protocols are improved swallowing and speech outcomes with excellent local oncologic control.

TORS IN RECURRENT OROPHARYNGEAL CANCERS

Transoral surgery has been adopted by many cancer centers with a growing number of series published with good oncologic and functional outcomes. The use of TORS for salvage of oropharyngeal cancers after radiation failure is not as well reported, but has important clinical implications. In the recurrent setting, there are many factors that can lead to increased difficulty with a transoral surgery. First, exposure of the tumor can be more difficult owing to radiation fibrosis and trismus which limits access of the robotic instrumentation. Additionally, mucosal edema and skip lesions may obscure the tumor boundaries, necessitating wider margins. Another consideration is that dissection in the proximity of the internal carotid artery can be riskier owing to obliteration of dissection planes from radiation. There is also the consideration that the radiated tissue will not heal as well, which increases the risk for oropharyngeal hemorrhage and delayed wound healing by secondary intention.

Although the data have been limited, there is increasing expansion of indications in carefully selected salvage cases. One case series of 64 patients who had TORS for salvage surgery compared to 64 patients with traditional open salvage approaches, showed an improved rate of tracheostomy use, feeding tube dependence, hospital stay, blood loss, and positive margin rate. The TORS group also had a better 2-year recurrence free survival rate (74% vs 43%) [44]. Although this study was not randomized and is subject to selection bias, it demonstrates the feasibility and oncologic success of TORS for recurrent cancers. This has been validated by other studies with positive margin rates around 7% with acceptable functional outcomes in swallowing, trach dependence, and safety [45, 46].

Studies have shown a low rate (1.4-7.5%) of minor or major oropharyngeal bleeding after transoral surgery [47, 48]. Although the bleeding rate was not statistically significant between salvage surgeries and primary surgeries [47, 48], there was a 1% rate fatal oropharyngeal hemorrhages in the salvage setting, which was the highest risk for advanced stage and pyriform sinus tumors [49]. Data is currently being collected as to whether prophylactically ligating the facial and lingual artery will decrease this risk.

Careful patient selection must be used when determining candidacy for transoral surgery in the salvage setting, but oncologic and functional results compare favorably to traditional open approaches. Particular attention must be made for hemostasis and prophylactic artery ligation to prevent life-threatening post-operative hemorrhage. It is now recommended to prophylactically ligate the ipsilateral facial and lingual artery at the time of neck dissection to

reduce the risk of severe oropharyngeal hemorrhage. In addition, visualized vessels in the tongue base and tonsillar defect require mechanical clips. Caution should be used in selecting patients for transoral robotic surgery if they have pre-existing coagulopathy, anticoagulation medications, uremia, or cirrhosis due to the risk of life-threatening bleeding.

FUTURE DIRECTIONS AND ONGOING RESEARCH

HPV related oropharynx cancer is more responsive to surgery and radiation than smoking related cancers, which has led to improved prognosis for these patients. With the biology of these tumors being different, the goals of care have shifted to achieving the same oncologic outcomes but reducing treatment morbidity by de-escalating therapy. A large randomized control trial ECOG 3311 utilizing transoral surgery for HPV related oropharynx squamous cell carcinoma is underway. The primary objective is to evaluate the 2-year progression free survival, swallowing, and quality of life in patients treated with adjuvant low-dose (50Gy) radiotherapy versus standard dose (60Gy) in intermediate risk patients. In this study, patients with T1 and T2, N1-N2b disease undergo transoral resection and neck dissection. If they have low risk tumors (N0-N1, negative margins, no extracapsular extension), they are observed with no adjuvant therapy. Patients with high risk tumors (>1mm extracapsular extension, 5 or more metastatic lymph nodes, or positive margins), undergo concurrent chemoradiation with 66Gy. Those patients who fall into an intermediate risk category are randomized to adjuvant radiotherapy of 50 or 60Gy and followed for 2 years. This study provides an exciting opportunity to de-escalate therapy for patients' whose treatments are currently based on historical data for smoking related cancers. The molecular biology of HPV related and smoking related cancers differs, resulting in different tumor behavior and treatment response, so separating these clinical entities and tailoring treatment may result in persistence of good oncologic outcomes with reduced treatment related morbidity.

Another avenue of ongoing development is in the re-design of the robot being used. The most commonly used DaVinci Si system requires 3 arms to enter the mouth, which results in a tight working space and instrument collisions. In addition, patients with poor neck extension, large tongues, trismus, or anterior larynx can be difficult to expose with the current instrumentation. Ongoing efforts to develop a single-port system that will deploy 3 arms and a camera are underway, which will likely result in a shorter set-up time and more efficient use of the limited workspace for tumor extirpation.

The evolving technology has potential to utilize the transoral approach for greater proportion of patients and with tumors deeper in the aerodigestive tract. This could include improved access to the nasopharynx, hypopharynx, and larynx, which are difficult to access with current instrumentation. While progressing in the transoral surgery realm, it will be important to continue to collect safety, oncologic, and functional outcome data to provide the best treatment options for our patients.

ABSTRACT

With any new or emerging technology, especially ones that may be paradigm shifting, come the rightfully asked questions, "Is this really going to be an improvement?", or "Are the benefits worth the trouble/cost?", and "What are the relevant applications?" Every aspect of robotic surgery has been under investigation since it stepped on the scene. The greatest challenge for early adopters of robotics, and even for the current generation of robotic surgeons, is how to fully incorporate this still burgeoning technology into our surgical culture's future from an academic, clinical, financial, and administrative perspective. It is the aim of this chapter to realize our robotic evolution while openly addressing its challenges now and in the future.

EVOLUTION

The history of surgical innovation was assessed and discussed by Riskin et al in 2006 [1]. The concepts of *enabling technology* and *disruptive technology* were presented; as was the impact upon adoption rates and market share. *Enabling technology* not only allows one to improve one's current performance, but also helps develop new abilities. In the field of surgery, enabling technology can be utilized to perform more complex procedures minimally invasively and to improve outcomes. Minimally invasive surgery (MIS) pulmonary sleeve resections, neo bladders, Whipple procedures, and redo surgery are now possible to a greater number of surgeons. *Disruptive technology* has the potential to topple industry leaders and change market shares. Focusing on emerging markets, these new innovations start slowly, and eventually pass their competitors [1].

Disruptive technology such as the introduction of laparoscopic instrumentation and laparoscopic surgery, was often met with skepticism, meticulous oversight (thoroughly necessary), and appropriate critique. After all, before any new skill is ever acquired comes unfamiliarity, frustration, practice, and finally competence. Early utilization of laparoscopic technique for cholecystectomy was associated with increased rates of common bile duct injuries, when compared to open surgery. With experience, and progression along the learning curve, the incidence of bile duct injuries did decrease [2]. The majority of bile duct injuries are the results of visual misinterpretation, which can be mitigated with cognitive map timeouts where the critical anatomy is reassessed prior to proceeding with the procedure [3, 4]. The appropriate spotlight on these outcomes led to improvement in training. With experience, the rates of common bile duct injuries associated with laparoscopic surgery decreased, becoming similar to that of an open approach [5]. The learning curve has been studied for virtually every surgical procedure where robotics is used and, does not take as long to overcome as one might assume.

For robotics to even stand a chance at being accepted by conservative surgeons, it had to achieve results equal to, or greater, than that of both open and current minimally invasive surgery or it would be disregarded—nothing more than an exorbitant gadget.

Studying a group of surgeons with varying degrees of laparoscopic expertise, Chang *et al.* observed similar times and scores in robotic vs. laparoscopic knot-tying tasks, after only 4-6 hours of robotic training. Furthermore, after an additional 2-4 hours of robotic training their times and scores significantly improved, surpassing their previous laparoscopic skills, suggesting robotics may be easier to learn than laparoscopy [6].

Melfi and Mussi highlight the importance of standardizing procedures and establishing operative schemes to ensure safety and surety in robotic surgery. They propose that it takes approximately 20 days, or 20 procedures, for both the surgeon and his team to complete adequate training. This learning curve is not only for the surgical procedure itself, but includes robotic setup, optics setup, trocar placement, patient positioning, and robot cart positioning [7]. Though their study was based on lung lobectomy, the principles established are universal and the learning curve identified was found to be similar in other cases including thyroidectomy, colorectal resection, and gynecologic procedures [8-10].

Management of complications is initially impacted through identification of anatomy and avoidance of the injury. Intraoperative recognition of the injury can lead to repair and, hopefully, mitigation of the impact of the injury. Although uncommon, bleeding remains the

most dreaded minimally invasive complication. With experience, management of bleeding can be performed robotically [11]. Cerfolio described the 4 P's: poise, pressure, preparedness, and proximal control to manage intraoperative thoracic vascular injury successfully. These principles are applicable to other specialties.

Fortunately, there are ways to practice robotic skills without fear of making a mistake and harming a patient. Open access simulations provide the ability to progress along the learning curve at will. While wet and dry labs allow the practice of basic skills with the actual clinical robot, virtual reality provides the opportunity to practice entire surgical procedures with a simulated robot in a simulated patient. Both have merit along with their disadvantages, thus a multifaceted approach to training is likely to yield optimum results [12].

A learning technique used in every professional sport to critique and guide practice is video review and feedback (i.e. game film). Carter *et al.* applied this "game film" concept to robotic surgery training and demonstrated that peer reviewed videos accelerated residents' progression along the learning curve [13]. Unfortunately, because robotic surgery is not fully adopted as part of all residencies, there is no universally accepted curriculum [14]. Though, as interest in robotic surgery continues to grow along with the development of new technologies, it is only a matter of time before formal training in robotics is commonplace in residency. In fact, some programs have already composed robotic curricula and avouch that safe implementation, even in the small community hospital setting, is entirely feasible [15-18].

Finally, as technology advances, along with surgical instrumentation and image guidance systems, surgical procedures and outcomes may become more consistent with decreased operator variability. Surgical simulators are used not only to train surgeons on the correct utilization of the instrument but can also facilitate procedural development. 3-D and 4-D reconstructed CT scans can be utilized for preoperative planning but may one day be seamlessly integrated into the video image to guide surgical procedures beyond the capabilities of current platforms, creating a virtual roadmap of surgery beyond what is visible to the naked eye.

CHALLENGES

Adopting and incorporating new technology into the operating room can be extremely polarizing. Resistance to change must be challenged by enthusiastic supporters of a new disruptive technology. The successful adoption of robotic assisted surgery requires intensive team management as well as risk assessment and mitigation strategies. Inevitably, obstacles will arise and must be overcome through a team-based approach.

As opposed to risk avoidance, another risk management strategy can be described as mitigation of risk. This approach revolves around learning as much as you can about the new surgical technology by following the training pathway, which routinely employs online learning, laboratory training with robotic technology, case observations, and proctored surgical procedures.

Current digital media as well as the Internet provides a great venue to view surgical videos. Surgical societies and journals provide peer-reviewed videos which can be extremely valuable to review and learn procedures. Finally, for the surgeon who is embarking on a robotic assisted pathway, it is extremely important that those surgeons consider incorporating

the robot assisted platform into procedures which they are already performing routinely and competently, so the stress associated with this new technology is not compounded by the concomitant need to learn and perform a new surgical procedure.

Early experience with robotic assisted surgery requires following the path of an "all in" strategy. A crucial step in the safe adoption of robotic assisted surgery is aligning the shared vision and common purpose of the nursing team, anesthesia team, as well as the bedside assistant surgeon. Each team member is encouraged to speak up during the procedure with any questions or concerns. They must also learn a new room set up, including new instruments, while adapting to the surgeon sitting at the console a short distance from the field. By aligning the core team members, the growing pains experienced by the OR team can be overcome as they progress through the learning curve together.

Eventually, the setup and docking of the robot become fluid and effortless, anesthesia learns the subtle nuances that distinguish a robotic assisted case from a non-robotic case, and the bedside assistant becomes comfortable with changes associated with the surgeon not being directly across from them. Having a dedicated and consistent bedside assistant is important to maximize efficiency and minimize operative times. Surgical residents should first be trained as bedside assistants, but ultimately sit at a dual console system and train as robotic surgeons. Learning curves may be helpful to gauge the ability of a surgeon to proficiently perform a specific procedure. However, many experienced robotic surgeons continue to improve over time without a plateau in the curve.

The added costs of a robotic assisted platform including acquisition, maintenance, instrumentation, and potential additional operating room time must be considered in light of the effectiveness of the procedure [19]. Once purchased, the cost of robotic assisted platforms, such as da Vinci (Intuitive Surgical, Sunnyvale, CA), are offset by enhanced utilization.

Early adopters become obligate team leaders and experts in room setup, operating room efficiency, minimization of instrument usage as well as members of robotic surgical committees. Through participation in robotic steering committees, the surgeon leader interfaces with anesthesia colleagues, nursing leadership, as well as administrative leaders including financial officers. Robotic steering committees provide the framework in a multidisciplinary fashion to help maximize outcomes, standardize care, and minimize cost. It is through this group where credentialing and re-credentialing protocols are developed, OR efficiency is measured, and outcomes and cost are addressed. Through these relationships, meaningful progress can be made in regard to preservation of excellence in outcomes and minimization of cost.

The da Vinci robot is the leader in the field with the greatest market share, but as competing robotic platforms are introduced, the cost of robotic assisted surgery to healthcare systems will likely decrease. As cost becomes less of a concern and outcomes are improved, the surgeon is left to view robotic assisted surgery as enabling technology. Once competent and efficient in routine procedures, the surgeon can expand the scope of minimally invasive surgery and realize new goals.

THE FUTURE

The goal of individual surgeons is to become better, more efficient, and less invasive. Standardizing surgical procedures such that there is less variance would allow for the development of consistent hyper-performers: best surgeons with best outcomes. More than the development of smaller instruments, the emphasis should and is becoming directed towards the further development of preoperative imaging (3D and 4D CT scans) to guide the surgeon in preoperative planning and intra-operative decision making. Enhanced communication with the OR team as part of the time out further engages OR team as valued members, which provides the potential benefit of enhanced team building, job satisfaction and outcomes.

Working collaboratively with industry, managing conflicts of interest as well as potential bias, preoperative imaging should, and one day will, be merged with the surgeon's visual field; utilizing real time fusion of the preoperative imaging, as opposed to picture in picture, will potentially not only provide a roadmap of critical structures, but could be used to deliver a guided path to the performances often necessary to attain best outcomes.

Incorporation of technology such as Doppler ultrasound to the top of instruments would further assist the surgeon by identifying soon to be divided structures as vascular or safe to divide. As Matisse once said, "I don't paint things, I only paint the difference between things." Great surgeons do not dissect structures directly, they dissect or more precisely dissect and divide the tissue between critical anatomical structures.

The incorporation of artificial technology and augmented reality should facilitate the adoption of minimally invasive approaches to all procedures. Developing augmented reality could be utilized to game-ify surgery such that the surgeon could perform multiple simulated surgeries tailored to the specific patient's imaging; the ultimate in personalized surgery.

Developing new controllers to guide the instruments may further change the way we perform surgery and may provide a mechanism, whereby, if we can align the doctor patient relationship, ethics, insurance and the law, perhaps, instead of advising so many of our colleagues, who call for intra-operative advice, we may be able to assist our colleague with real time proctoring and/or assistance in the OR to optimize patient outcomes.

CONCLUSION

Surgical robotics is becoming less invasive, deliberately intelligent, and strikingly visceral. Features such as image-on-lay, global positioning system (GPS) map of operative field, data integration, artificial intelligence, automated surgery, tumor margin assessment will be standard features of the future operating platform. With robotic technology evolving so precipitously, it is impossible to tell where we will be in 10 years, let alone 50 years. Regarding the laparoscopic revolution only 30 years ago, Dr. Jacques Perissat insightfully urged us all, "...for the first time, surgery no longer involves any physical contact between the surgeon's hand and his patient. Let us hope that this will not lead to total absence of a human relationship in the surgical operation" [20].

INTRODUCTION

In 2000, the da Vinci Surgical System became the first, and only, approved robotic system by the US Food and Drug Administration (FDA) for general laparoscopy. Five years later, the FDA extended its approval to include gynecologic surgery. Since then, over three million robotic cases have been performed worldwide [1]. In the U.S. alone, it is estimated that more than 2,025 hospitals offer robotic assisted surgery [2]. With gynecologic surgery making up over 50% of robotic cases in the U.S., its application in the field of gynecology has grown exponentially [1].

The advantages of robotic surgery have allowed more gynecologic surgeons to feel at ease with laparoscopic surgery. Robotic surgical techniques have been described for a wide range of gynecologic surgical conditions from abnormal uterine bleeding, fibroids, endometriosis/adenomyosis, ovarian cysts, infertility, pelvic organ prolapse and malignancy. This has resulted in an increase in minimally invasive surgery and a decrease in open abdominal surgery.

Despite its growing popularity, the use of robotic assisted laparoscopy has been controversial. When a vaginal route is not feasible or safe, the American Congress of Obstetricians and Gynecologists (ACOG) advocates for laparoscopic surgery over open abdominal surgery; however, its stance on the role of robotic assisted laparoscopy remains mixed [2, 3].

From a technology stand point there are many advantages to the robotic system over conventional laparoscopy. The three-dimensional view improves the surgeon's visual spatial orientation and overcomes the depth limitations of traditional two-dimensional laparoscopy. The Endo-wrist technology with 7 degrees of freedom allows for superior freedom and

dexterity, allowing for more facile complex dissection. The robotic arms eliminate operator tremors, while reducing surgeon fatigue. For those in practice with limited assistance, the robotic system also allows the primary surgeon to control the camera and up to 3 instruments at a time. These benefits are particularly useful in the obese patient [1, 4]. The dual console system also facilitates the practical education of a new learner.

When looking at patient and operative outcomes in benign gynecologic surgery, robotic assisted laparoscopy and conventional laparoscopy appear to be comparable, with some studies suggesting superior outcomes in robotic assisted procedures. Both surgeries afford minimal estimated blood loss, safe same-day discharge, early patient mobilization, decreased post-operative complications, improved quality of life, similar rate of conversion to open surgery and overall decreased patient morbidity [5–8]. Studies also show decreased post-operative pain in those undergoing robotic assisted surgery, resulting in decreased need for analgesics and shorter hospitalizations [1, 8]. This is thought to be due to decreased irritation and increased tissue protection afforded by the remote center.

While the advantages of the robotic system are vast, there are disadvantages. When the robotic system was first on the market, many found the docking process to be time consuming and cumbersome. The system is viewed as bulky, as it requires a patient side cart, surgical console as well as trained specialty support staff. The lack of tactile feedback can also pose challenges to the operator. However, as the surgical community gained more experience and the technology advanced from the Si to the Xi system, many of these difficulties were overcome. A randomized control trial by Deimling et al. found that when performed by an experienced surgeon, there was no statistically significant difference in operating time between robotic-assisted laparoscopic hysterectomy and standard laparoscopic hysterectomy [9].

In the gynecology literature, the cost of robotic surgery is the most commonly cited deterrent for use. The system is associated with high equipment costs, maintenance fees and utilizes disposable parts [6]. Multiple cost analysis studies have been conducted, with varying conclusions. While utilizing the robot may increase equipment costs, many argue that shorter operative times, decreased hospital stay and complication rates may make up the cost difference. A study by Moawad et al. found that robotic hysterectomies for uteri weighing greater than 750 grams was found to have an improved cost profile [10]. This suggests that in the appropriate context, robotic surgery may be more financially sound. Therefore, utilization of robotic surgery in gynecology should be based on the individual patient, surgeon skill, support staff, and equipment availability.

While the debate between robotic assisted laparoscopy vs. conventional laparoscopy still remains, the utilization of robotic assisted surgery continues to grow, forever changing the practice of minimally invasive gynecologic surgery.

GYNECOLOGIC SURGICAL ANATOMY

Upon entry into the abdomen, a survey of the abdomen and pelvis should be performed. To best view the pelvic anatomy, the patient should be placed in appropriate Trendelenburg and the bowel swept out of the pelvis.

If present, the uterus sits between the bladder and the rectum. It is made up of the fundus, corpus and cervix. It is supported by a series of ligaments (Figure 1). The round ligament of

the uterus sits just anterior of the fallopian tube and exits the pelvis through the deep inguinal ring. This ligament helps to maintain the anteversion of the uterus. Connecting the uterus to the lateral pelvic sidewalls on either side of the uterus and cervix are the broad ligament and cardinal ligament. The uterosacral ligaments run posterior from the posterior cervix to the anterior sacrum. Together, the uterosacral and cardinal ligaments help provide pelvic floor support to the uterus and prevent prolapse.

Figure 1. Laparoscopic view of normal pelvic anatomy. U = Uterus; RL = Round Ligament; UOL = Utero-Ovarian Ligament; FT = Fallopian Tube; C = Cervix; O = Ovary; USL = Uterosacral Ligament; R= Rectum.¹

The adnexa are comprised of the fallopian tubes, ovaries and their supporting structures. The fallopian tube is ~10cm in length and is separated into the isthmus, ampulla, infundibulum and fimbria (Figure 2). They are connected by the mesosalpinx and insert into the uterus at the cornua. The ovaries attach to the uterus via the utero-ovarian ligament. The infundibulopelvic (IP) ligament, also known as the suspensory ligament, contains the ovarian vessels and connects the ovary to the pelvic sidewall.

The distal half of the ureter runs through the pelvis. It crosses the pelvic brim and enters the pelvis anterior to the bifurcation of the common iliac artery. The IP ligament sits superior and lateral to the ureter. As the ureter courses lateral to medial, it travels along the pelvic sidewall in the infraovarian fossa. At the level of the cervico-uterine junction, the ureter crosses just below the uterine artery. It then travels along the cardinal ligament before entering the bladder trigone.

The rectosigmoid colon is attached via physiologic adhesions to the left pelvic brim. It descends posterior to the uterus and below the uterosacral ligaments. The bladder sits anterior to the uterus. An avascular space known as the vesico-uterine space sits between the two. This space is used to dissect the bladder off of the uterus and cervix at the time of hysterectomy.

TECHNIQUES AND CONSIDERATIONS FOR GYNECOLOGIC SURGERY

Positioning

All surgery begins with proper positioning of the patient. Poor patient positioning can result in long-term nerve damage, facial trauma and unnecessarily difficult surgery. When utilizing the robotic platform, access to the surgical field must also be considered for the robotic arms and camera.

In gynecologic surgery, the dorsal lithotomy position is favored. Most gynecologic surgeries require uterine manipulation or delineation of the bladder. The dorsal lithotomy position allows for ease of access to the vagina and bladder.

When positioning the legs, Allen Yellofin stirrups (Allen Medical Systems Inc, Acton, MA, USA) are used. For larger patients, Allen Ultrafin stirrups (Allen Medical Systems Inc, Acton, MA, USA) may be used. Care should be taken to align the patient's ankle, knee and contralateral shoulder. The patient's ankles rest at a 90-degree angle in the stirrup. The knees are bent between 70-90 degrees. In high lithotomy, the maximum hip flexion should be 90 degrees. When the patient is in low lithotomy, the hip should not extend greater than 120 degrees. The distance between the legs at the perineum should be 90 degrees. Points of

pressure should be avoided, regardless of the position of the legs. Hyperextension, hyperflexion and excessive pressure of the lower extremities can result in permanent nerve damage to the femoral, lateral femoral cutaneous and common peroneal nerves.

The patient's buttocks should be resting at or slightly over the table's edge. Care should be taken to assess adequate lumbar and sacral support. This allows for placement and adequate usage of a uterine manipulator. Access to the perineum and vagina also allows for ease of specimen removal through this orifice when indicated.

In order to achieve optimal access to the patient, the arms should be tucked. The patient's arms should rest straight with the thumbs aiming upward. The wrists should also be placed in an anatomically neutral position. This can be achieved with a sheet, foam padding or padded arm sleds. Once the arms are padded and tucked, the patient's IV and blood pressure cuff should be checked to ensure that they are optimally functioning.

As the patient will be placed in Trendelenburg, care should be taken to prevent the patient from sliding on the operating table. There are a variety of ways this can be achieved ranging from egg crate foam, the Bean Bag Positioner (AliMed Inc, Dedham, MA, USA), to the Pink Pad (Xodus Medical, New Kensington, PA, USA) memory foam system. Regardless of which system is used, it is recommended a tilt test be performed. This ensures that the patient is secure on the table and is able to tolerate Trendelenburg prior to starting the procedure.

Special consideration to the patient's face, in particular the eyes, need to be taken in robotic assisted surgery. The surgeon is removed from the bedside and is less aware of the extracorporeal movements of the robotic arms and camera. Therefore, the patient's face should be adequately protected. A foam mask or placement of a Mayo stand above the patient's head can be utilized [11]. Tam et al. describe a modification of the Head Butler (Tri-Medical Corporation, Portland, OR, US) that allows for protection of the patient's face and chest, while providing a platform for placement of instrumentation [12].

Abdominal Entry and Trocar Placement

Prior to the start of the procedure, it is recommended that a pelvic examination be performed under anesthesia. This allows the surgeon to assess the shape and mobility of the uterus, adnexa and any other palpable pelvic pathology and better plan for appropriate port placement [13]. An orogastric tube should be placed prior to abdominal entry to decompress the stomach [14]. Once the patient is prepped and draped, the bladder should be drained with a Foley catheter. An indwelling catheter should be considered for longer cases or if back filling of the bladder is anticipated. If indicated, a uterine manipulator can then be placed at this time.

Trocar insertion is often viewed as the most hazardous part of laparoscopy as it accounts for up to 40% of laparoscopic complications [15]. The literature does not support the superiority of Veress needle, open laparoscopy or direct trocar entry over the other [14]. Therefore, initially entry into the abdomen should be undertaken based on surgeon experience and patient history. In patients with a complex surgical history, Palmer's point is often favored as the safer initial point of entry over the umbilicus [15]. Once access has been safely achieved, all subsequent trocars should be placed under direct visualization to avoid any unnecessary injuries to the surrounding structures and organs.

Figure 3. Port Placement.

For the vast majority of gynecologic surgery, the lower uterine segment and cervix serve as the focal point [13]. Therefore, the camera is most commonly placed at the umbilicus. Large pathology may warrant placement of a supraumbilical port in order to achieve adequate visualization. Once the endoscopic port is placed, two 8-mm ports are placed in the right and left lower quadrants under direct visualization. These ports should be placed approximately two finger breaths medial and superior to the anterior-superior iliac spines, while maintaining a minimal distance of 8-10cm between the endoscope and focal point [11, 13]. The assistant port should be placed in the left upper quadrant, taking care to triangulate between the endoscopic and left lower quadrant port. If the fourth robotic arm is needed, the port should mirror the assistant port on the contralateral side [13]. When determining trocar placement, the anterior abdominal wall anatomy should always be assessed to minimize the risk of a vascular or nerve injury (Figure 3).

Docking

Once the ports are placed, the patient should be placed in appropriate Trendelenburg position. Atraumatic laparoscopic instruments can be utilized to sweep the bowel out of the surgical field and into the upper abdomen. The patient's bed should be positioned to allow adequate space for the robotic system to be docked.

While the robotic system can be either center or side docked, side docking is preferable in gynecology. This allows for assistant access to the pelvis for uterine manipulation and specimen removal. The cart can be docked on either side of the patient, based upon surgeon preference and handedness.

ROBOTIC ASSISTED TOTAL LAPAROSCOPIC HYSTERECTOMY

With over 600,000 cases per year, the hysterectomy is one of the most commonly performed surgical procedures in the United States. This accounts for more than \$5 billion health care dollars [16]. The fast learning curve and advantages of the robotic system is thought to have made the minimally invasive hysterectomy more attainable to those less apt at conventional laparoscopy [17]. In 2015, 263,000 hysterectomies were performed robotically [13]. Thus, the robotic platform plays a significant role in the minimally invasive hysterectomy.

Indications

Indications for a benign hysterectomy range from recurrent cervical dysplasia, endometriosis, chronic pelvic pain, pelvic organ prolapse and abnormal uterine bleeding. Symptomatic uterine leiomyomas are the most common reason for a hysterectomy [3, 18]. Regardless of the indication, multiple studies have been performed confirming the benefits of a minimally invasive hysterectomy.

When undergoing a minimally invasive route, patients can have a same-day discharge, decreased post-operative pain, minimal blood loss and improved patient satisfaction compared to an open abdominal approach. When looking at standard laparoscopic hysterectomy versus robotic-assisted laparoscopic hysterectomy, the studies suggest that the two are comparable [6, 13, 17]. A multicenter analysis performed by Lim et al. found that with high-volume experience, robotic-assisted benign hysterectomies may provide improved outcomes when compared to vaginal, abdominal and conventional laparoscopy [7].

While the robotic system can be utilized for straightforward hysterectomies, its advantages are maximized in the more complex cases. Patients with a history of multiple abdominal or pelvic surgeries, advanced endometriosis or pelvic inflammatory disease/tubal ovarian abscess are at a higher likelihood of having severe adhesive disease. This agility and fine dissection capabilities of the robotic system can help facilitate safe lysis of extensive adhesions caused by an adverse medical or surgical history.

For enlarged uteri, it was previously thought that the upper limit for a minimally invasive approach was greater than 15 weeks gestation or weighing >500 grams [19]. With the advancement in laparoscopic skills and technology, these boundaries have been pushed to uteri well beyond 1,000 grams. Utilization of the robotic fourth arm can aid in the manipulation of heavy pathology and helps decrease assistant and surgeon fatigue. However, if the fundus approaches the costal regions, safe port placement cannot be achieved and an open approach should be undertaken. A robotic approach is also unlikely to be successful if the width of the uterus limits mobility and access to the pelvic sidewalls.

Surgical Techniques

The steps for a robotic assisted total laparoscopic hysterectomy mirror that of a conventional laparoscopic and abdominal hysterectomy.

Upon entry into the peritoneum, a global assessment of the abdomen and pelvis should be performed. Care should be taken to identify the ureters prior to beginning the hysterectomy. As the robotic platform is often favored for complex patients with suspected adhesive disease, retroperitoneal dissection with ureterolysis may need to be performed. Should the pelvic anatomy be significantly distorted, it is recommended that the anatomy be normalized prior to proceeding.

Once the anatomy has been normalized, the round ligament is grasped and transected. For those patients undergoing a salpingo-oophorectomy, the infundibulopelvic (IP) ligament is then isolated, taking care to dissect it away from the ureter. Upon isolation, the IP ligament is carefully transected using the surgeon energy source of choice. For those retaining their ovaries, it is recommended that a prophylactic salpingectomy be offered to decrease the risk of ovarian cancer [20]. This is accomplished by identifying the fimbria and serially transecting the mesosalpinx. Once the fallopian tube has been detached close to the cornua, the utero-ovarian ligament can then be desiccated and transected.

Once the adnexa and the round ligament are detached, the leaves of the broad ligament begin to fall open. The anterior and posterior leaves of the broad ligament are then opened and transected to expose the lateral uterine anatomy. The vesicouterine peritoneal fold is then identified and transected to create a bladder flap. The vesicouterine space is then developed and the bladder dissected off the uterus and cervix.

The uterine vessels are then skeletonized prior to their ligation. Care is taken to ligate the uterine vessels as proximal to the uterine corpus as feasible. At the level of the cervicouterine junction, the ureters run 1.5-2cm below the uterine artery and are at high risk for injury during transection of the uterine vessels. The cardinal ligament is then cut down to the level of the uterosacral ligament. Each successive bite is taken medial to the previous, resulting in lateralization and protection of the ureter.

Once both sides of the uterus and cervix have been taken down and the bladder flap completed, the colpotomy can then be made. Upward tension is crucial at this stage, whether provided from a uterine manipulator with a colpotomy cup or a sponge stick. This tension allows for lateralization of the ureters and defining anatomical landmarks, in particular the cervicovaginal junction. After completion of the colpotomy, the specimen can then be passed through the vaginal opening to be assessed by pathology. Larger specimens can be removed via a mini-laparotomy or contained, manual morcellation. Please refer to the leiomyoma section of this chapter for further details.

The vaginal cuff can be closed in a variety of ways. Techniques include, a running stitch, serial figure-of-eight stitches and closure in one vs. two layers. If available, barbed suture should be utilized as studies have shown it to decrease operative time, blood loss and vaginal dehiscence rates [21–23]. To reduce the risk of post-hysterectomy apical prolapse, it is recommended that uterosacral ligament suspension be considered at time of vaginal cuff closure [24].

At the conclusion of the hysterectomy, a cystoscopy should be performed to assess ureteral and bladder integrity. The ureter's close proximity to the pelvic organs places it at risk for damage. Ureteral injuries are classically described as occurring at one out of four times during a hysterectomy—transection of the infundibulopelvic ligament, ligation of the uterine artery, at the level of the uterosacral ligaments, and at the time of vaginal cuff closure. While cystoscopy will not rule out a delayed thermal or ischemic injury, it will aid in the

diagnosis of a transection or suture ligation injury. Indigo carmine, Methylene blue or Phenazopyridine can be used to dye the urine and better visualize ureteral jets.

ADNEXAL MASSES

Adnexal masses are commonly encountered. It is estimated that 289,000 women undergo evaluation for an adnexal mass annually [25]. In the United States, it is estimated that up to 10% of women will undergo surgery for an adnexal mass [25].

Clinical Assessment of Adnexal Masses

Due to concerns for underlying malignancy, adnexal masses often provide diagnostic and management quandaries. When working up an adnexal mass, the goal is to determine the likelihood the mass is malignant or benign. Patients with ovarian cancer have improved overall survival rates when managed with or by a gynecologic oncologist [26]. Therefore, those patients who are suspected to have an underlying malignancy should be referred to a gynecologic oncologist.

The most important independent risk factor for ovarian cancer is age, as the incidence sharply increases after menopause [25, 26]. The most important personal risk factor is a strong family history of breast or ovarian cancer. 9-24% of epithelial ovarian cancers are due to BRCA 1 or 2 germline mutations [27]. Therefore, a thorough personal and family history is crucial.

The differential diagnosis for a benign adnexal mass is broad and includes, functional cysts, hemorrhagic cysts, endometriomas, mature teratomas/dermoid cysts, serous cystadenomas, mucinous cystadenomas, hydrosalpinx, paratubal cysts, ovarian remnant, tubo-ovarian abscess, ovarian torsion and ectopic pregnancy. Therefore, the clinical presentation is often varied and reflective of the diagnosis. Patients report symptoms ranging from acute to chronic pain, pressure (due to mass effect) and dyspareunia. If due to an infections process, some may experience general malaise with nausea and vomiting. All women of reproductive age should undergo a pregnancy test to assess for an ectopic pregnancy. Symptoms of bloating, abdominal or pelvic pain, difficulties with the bowels and bladder, early satiety and weight loss may be concerning for an ovarian malignancy, particularly in the post-menopausal patient.

While a thorough pelvic exam is recommended for all patients, the exam is often limited by the patient's body habitus, especially in patients with a BMI >30 [26]. If the adnexa are palpable, findings of irregular borders, limited mobility, solid consistency, nodularity, bilaterality and ascites are concerning for malignancy. However, these findings can also be found in benign pathology such as endometriomas, infectious processes, hemorrhagic corpus luteum and leiomyomas [26]. Therefore imaging plays a critical role in the work-up of an adnexal mass.

If the overall clinical picture is suspicious for an underlying malignancy, tumor markers can be obtained. CA 125 is most commonly associated with epithelial cancers of the ovary. It is more specific and has a higher positive predictive value in the post-menopausal patient

[26]. If the clinical picture is more suggestive of a malignant germ cell tumor, a beta-hcg, alpha-fetoprotein and L-lactate dehydrogenase can be considered. Abnormal or postmenopausal bleeding, signs of hyperestrogenism and a solid pelvic mass are consistent with a granulosa cell tumor. In this instance, an inhibin level should be obtained.

Imaging of Adnexal Masses

Ultrasound is the imaging modality of choice in gynecology. When assessing the adnexa, a transvaginal approach is favored. Ultrasound allows for the evaluation of size, composition and vascular characteristics of the adnexal mass in question.

Ultrasound findings concerning for malignancy are size >10cm, papillary or solid components, thick septations, ascites and high color Doppler flow [26]. However, some benign conditions will present with these findings. For example, mature teratomas will often have a solid component. Findings consistent with a benign etiology are thin, smooth walls, absence of solid components, absent of septations and lack of internal blood flow [26]. Endometriomas on ultrasound are hypoechoic with a uniform, 'ground-glass' appearance. Hemorrhagic cysts will have a fishnet or lacey, reticular pattern (Figure 4).

Figure 4. A: Simple ovarian cyst with anechoic fluid surrounded by a thin rim of ovarian tissue. B: Lacy reticular pattern of a hemorrhagic ovarian cyst.

While MRI and CT scans are not recommended to routinely assess adnexal masses, they do have a role in specific cases. If there is difficulty ascertaining the origin of the pelvic mass, an MRI is often superior to ultrasound at delineating the origin of the mass. When malignancy is suspected, CT imaging can evaluate for the presence of metastasis.

Management of Adnexal Masses

Currently, ACOG recommends the following patients with an adnexal mass be referred to gynecologic oncologist:

- Postmenopausal with elevated CA 125 level, ultrasound findings suggestive of malignancy, ascites, a nodular or fixed pelvic mass, or evidence of abdominal or distant metastasis.
- Premenopausal women with very elevated CA 125 level, ultrasound findings suggestive of malignancy, ascites, a nodular or fixed pelvic mass, or evidence of abdominal or distant metastasis.
- Premenopausal or postmenopausal with an elevated score on a formal risk assessment test such as the multivariate index assay, risk of malignancy index, or the Risk of Ovarian Malignancy Algorithm or one of the ultrasound-based scoring systems from the International Ovarian Tumor Analysis group [26].

Observation of an adnexal mass is indicated in the following situations:

- If the mass is benign appearing on imaging and examination and the patient is asymptomatic.
- Simple cysts measuring <10cm in size in both the pre- and post-menopausal patient.
- Patients deemed to be poor surgical candidates, secondary to multiple comorbidities suspected to result in significantly high morbidity and mortality if surgery were to be undertaken [26].

These patients can be monitored with repeat imaging. Currently, no standard interval or duration for follow-up ultrasounds have been defined [26]. If the patient is undergoing expectant management, they should be counseled on signs and symptoms of an ovarian torsion. Patients with adnexal masses measuring between 6 cm and 10 cm are at an increased risk for an ovarian torsion [28].

Surgical management should be considered in the symptomatic patient, especially if there is low likelihood of the mass spontaneously resolving. If feasible, a laparoscopic approach should be used when surgically managing these patients.

Surgical Approach to the Adnexal Mass

Surgical management of an adnexal mass can range from cystectomy, salpingectomy to oophorectomy depending on the etiology. In the adolescent patient and the patient desiring fertility, ovarian conservation should be prioritized.

Aspiration of a cyst should be avoided if there is any concern for malignancy. Indications for aspiration would be a tubo-ovarian abscess and diagnosis of suspected advanced ovarian cancer in patients who will undergo neoadjuvant therapy [26]. Drainage of benign simple cysts is not definitively therapeutic and is therefore recommended against.

Cystectomy

The vast majority of ovarian cysts are encapsulated with a layer of epithelium (Figure 5). An avascular space sits between this epithelium and cyst. The development of this space is critical when performing a cystectomy to avoid rupturing the cyst.

After careful assessment of the patient's anatomy, an incision is made along the antimesenteric surface of the ovary, taking care to minimize involvement of the extensive vascularity of the ovarian base [28]. This can be accomplished using monopolar scissors or an ultrasonic scalpel. The incision is carried through the ovarian stroma down to the level of the cyst wall and can be extended as needed to successfully enucleate the cyst.

Once the level of the cyst wall is reached, the cut epithelial edge is then grasped using a grasper, such as the fenestrated bipolar, Maryland or Prograsp. A combination of blunt and sharp dissection is then utilized to develop the avascular plane between the epithelium and cyst wall. Cautery can be used as points of bleeding are encountered. However, a cystectomy should have minimal blood loss if the correct plane is entered. The fourth robotic arm or surgical assistant can aid in stabilizing the adnexa and provide additional traction and counter traction for the dissection.

Figure 5. Left ovarian cyst.

Upon removal of the cyst, the surgical bed should be assessed for hemostasis. Once hemostasis has been adequately achieved, no further intervention is necessary. Despite its distended and splayed appearance, the ovary will return to normal proportions without surgical reapproximation [25].

Extreme caution should be used to avoid rupturing the cyst. Should this occur, the cyst wall should still be removed. By grasping the cyst wall and capsule near the plane of dissection, traction and counter traction can be applied to separate the cyst wall. If a mature teratoma ruptures at the time of removal, copious irrigation should be used to decrease the risk of developing a chemical peritonitis [28, 29].

Once the procedure has been completed, the specimen should be placed in an endoscopic specimen retrieval bag prior to removal. If the contained specimen is too large to be removed from the endoscopic port site, the incision can be enlarged, the cyst can be ruptured and

drained inside of the bag or contained hand morcellation can be performed if the cyst is solid [25]. Care should be taken not to damage the bag in this process.

Salpingo-Oophorectomy

Prior to beginning an oophorectomy, the course of the pelvic ureter and its relation to the infundibulopelvic (IP) ligament must be identified. The ureter runs close to the IP ligament and is at high risk for injury at time of oophorectomy. If indicated, the surgeon should be prepared to perform a retroperitoneal dissection to appropriately identify the ureter and create adequate space between the ureter and desired surgical site.

Once the ureter is safely away from the intended surgical site, the ovarian vessels are ligated within the IP ligament. The ligament is then transected. The posterior leaf of the broad ligament is then incised down toward the utero-ovarian ligament. Posterior to the round ligament, the utero-ovarian ligament and fallopian tube are then identified, grasped, cauterized and transected.

The ovary and fallopian tube can then be placed into an endoscopic bag and removed through an endoscopic port site.

Ovarian Remnant Syndrome

Ovarian remnant syndrome (ORS) is a rare condition in which women who have previously undergone an oophorectomy develop residual ovarian tissue. This often results in pelvic pain and an adnexal mass [30]. The mechanism of this disease is not well understood, but is thought to be due to incomplete removal of ovarian tissue on a microscopic level.

Patients with a history of endometriosis, pelvic adhesive disease, pelvic inflammatory disease or multiple pelvic surgeries are at higher risk for ORS [30, 31]. In a case series done by Benton et al. all patients with a pathologically confirmed ovarian remnant had a prior history endometriosis [32]. It is thought that anatomic distortion caused by these pathologies make it difficult to completely excise the ovary. This results in an increased risk for developing ORS [31]. Additionally, despite ligation of the ovarian blood supply, adherent ovarian tissue to the pelvic peritoneum or adjacent viscera can become neovascularized and responsive to gonadotropins [30].

If ORS is suspected, evaluation with a pelvic ultrasound, CT or MRI is warranted. A FSH and LH can be obtained; however, cases of ORS have been documented in patients with postmenopausal levels of FSH and LH [30, 31]. Ultimately, confirmation of an ovarian remnant requires pathologic diagnosis.

Patients with ORS most commonly present with pelvic pain and an adnexal mass. As a result, most opt to undergo surgical management. Laparoscopy provides optimal visualization, as remnants can be as small as a single centimeter. Due to the complex nature of ovarian remnant syndrome, robotic assisted operative laparoscopy is often preferred over conventional laparoscopy.

As patients with ORS often have a complex gynecologic and surgical history, adhesions are frequently encountered. The ureter is also at high risk of injury, as ovarian remnants are often found in the retroperitoneal space. Therefore, surgeons performing an excision of an ovarian remnant must be skilled at extensive retroperitoneal dissection and ureterolysis. If there is difficulty locating the remnant, pre-operative imaging can aid in locating the mass.

Once the remnant is found, care is taken to dissect it away from the pelvic sidewall and any vital structures, down to its blood supply (Figure 6). To decrease the risk of leaving behind remnants of the ovarian cortex, blunt dissection should be minimized [30]. After the blood supply is isolated, it is then ligated and transected. The remnant should then be placed in an endoscopic bag for removal.

Figure 6. Ovarian remnant dissected off the left lateral pelvic sidewall, down to its blood supply.

LEIOMYOMAS

Leiomyomas, also known as fibroids, are the most common benign tumors of the female genital tract. They are the leading indication for hysterectomy in the United States [33]. It is estimated that by the age of 50, 70% of Caucasian women and >80% of African American women will have leiomyomas [34]. This results in \$4.1 to \$9.4 billion dollars spent annually on the management of leiomyomas in the U.S. [33].

Figure 7. To the left is an image of a pedunculated uterine leiomyoma (P). To the left is an image of a subserosal leiomyoma.

Leiomyomas are the result of monoclonal proliferation of smooth muscle cells. They can be subserosal, submucosal, intramural and pedunculated in location (Figure 7). Leiomyomas are sensitive to ovarian steroid hormones, as they contain both estrogen and progesterone receptors. Risk factors for the development of fibroids include age, early menarche delayed pregnancy, decreased parity, caffeine and alcohol use, obesity and hypertension [33].

Clinical Assessment of Leiomyomas

While the majority of leiomyomas are asymptomatic, the two most commonly reported symptoms are abnormal uterine bleeding and pelvic pressure [34]. Patients often note heavy or prolonged bleeding that can result in significant iron deficiency anemia. The mass effect of leiomyomas can result in significant pelvic pressure, urinary frequency and obstruction, constipation and dyspareunia [34]. The size and location of the leiomyoma can also result in subfertility.

As most women will present with abnormal uterine bleeding, it is recommended an endometrial biopsy be obtained in all women over the age of 45 or those with risk factors for an underlying uterine malignancy such as obesity, polycystic ovarian syndrome or history of unopposed estrogen. Other causes of abnormal uterine bleeding should be ruled out as well. If the bleeding is significant or the patient is symptomatic, a CBC to assess for anemia is warranted. For patients reporting urinary symptoms or flank pain, assessment of the renal system is recommended to check for ureteral obstruction and hydronephrosis.

Figure 8. MRI of a grossly enlarged uterus due to multiple leiomyomas (L). ES denotes the endometrial stripe.

When leiomyomas are palpated on pelvic examination, the uterus typically correlates with a 12 weeks gravid uterus, at minimum [33]. The uterus will feel enlarged with irregular borders.

If leiomyomas are suspected, it is recommended that patients undergo a pelvic ultrasound. A saline infused hystrogram can be utilized to delineate submucosal fibroids. While CT scans have limited value in the evaluation of leiomyomas, MRIs can provide additional valuable information. MRI cannot only provide the size, number and vascularization of the fibroid, but it can provide a map of their location relative to the endometrium, myometrium and serosa (Figure 8) [18, 33]. This is particularly useful when planning a laparoscopic myomectomy.

Management of Leiomyomas

For women desiring fertility or declining hysterectomy, a variety of options exist for the management of leiomyomas. However, hysterectomy is the only option for definitive treatment and prevention of recurrence [34]. Given the adverse cost, long-term results and safety profile of most non-surgical options, most patients ultimately undergo some form of surgery.

In patients wishing to avoid surgery, medical therapy is geared towards the patient's symptoms. Contraceptive steroids can be utilized to control uterine bleeding. For those wishing to avoid hormones, tranexamic acid and non-steroidal anti-inflammatory drugs (NSAIDs) can be considered [33]. These methods have not been shown to decrease leiomyoma or uterine volume and often only provide short-term relief [34].

Gonadotropin-releasing hormone agonists (GnRHa) have been shown to reduce leiomyoma size and excessive menstrual bleeding. Within three months of treatment, a 35-65% reduction in volume can be seen [34]. These effects are temporary, with resumption of previous leiomyoma size upon cessation of treatment. In addition to its poorly tolerated hypoestrogenic side effects of hot flashes and vaginal dryness, long-term use of GnRHa can result in significant bone loss. For patients on GnRHa for greater than 6 months, add back therapy must be provided.

The optimal use of GnRHa is in the pre-operative period. For patients with significant anemia, this can provide patients time to improve their anemia and rebuild their iron stores prior to surgery. The ability to shrink fibroids and overall uterine size could also mean the difference between an abdominal vs. minimally invasive route of surgery. However, by distorting the planes of dissection, GnRHa can increase the difficulty of a myomectomy and the operating time [33, 35].

Uterine artery embolization (UAE) is another option for management of leiomyomas. Under fluoroscopic guidance, interventional radiologists utilize a transcutaneous femoral approach to access the uterine arteries. The uterine arteries are then embolized using polyvinyl alcohol particles of trisacryl gelatin microspheres, with or without supplemental metal coils [34]. This results in the devascularization and involution of leiomyomas. The most common complication from UAE is postembolization syndrome [18]. While successful pregnancies have been documented after UAE, this procedure has been associated with impaired ovarian reserve and increased pregnancy complications, in particular, abnormal placentation [34]. Limited data is available regarding pregnancy after UAE, and is generally recommended against or with caution [33, 34].

For patients desiring fertility or who wish to retain their uterus, myomectomy should be considered. Myomectomy has also been shown to improved pregnancy rates. The route of

myomectomy is dictated based upon the size and location. Submucosal fibroids that occupy the endometrial cavity can be managed via operative hysteroscopy. For intramural, subserosal and pedunculated leiomyomas, a laparoscopic approach should be taken if feasible. It is important to counsel patients that after myomectomy, the five year risk of recurrence ranges from 20-40% [18].

Robotic Assisted Laparoscopic Myomectomy

Despite its increased cost, some believe robotic assisted laparoscopic myomectomy to be superior to conventional laparoscopy [6]. The conversion rate to an open procedure is 0-5% for robotic assisted laparoscopic myomectomy vs. 11.3% for conventional laparoscopy [33, 34]. Robotic assisted laparoscopic myomectomy has been shown to have lower intraoperative blood loss and shorter length of hospital stay, while affording patients all the same benefits of the conventional route.

The benefits of the robotic platform are particularly pronounced during myomectomy. Suturing with conventional laparoscopy is often perceived as difficult and cumbersome. Robotic assisted suturing is more facile, resulting in improved quality of sutures [6]. As the closure of the myometrial defect at time of myomectomy often requires closure in multiple layers, this can make a significant difference. The improved surgical accessibility of the robotic system also helps to overcome difficulties such as posterior fibroids and obesity [2].

Myomectomy

Upon docking, the patient's anatomy should be adequately assessed. Preoperative imaging can be helpful in mapping the anticipated location of the leiomyomas. A variety of interventions exist to help decrease intraoperative bleeding including intrauterine injection of vasopressin, tranexamic acid, misoprostol and a tourniquet [33]. Each method carries its own unique risks and benefits and should be utilized per the surgeon's discretion.

Once located, an incision is made into the serosa and myometrium down to the level of the leiomyoma. While unipolar cautery can be used to accomplish this, studies have shown the Harmonic Scalpel to provide a cleaner dissection with less blood loss [33, 35]. When feasible, a transverse incision is recommended to facilitate suturing and knot tying [33].

After the hysterotomy is created, the myometrium will begin to retract. A laparoscopic tenaculum can be placed on the myoma for manipulation and creation of counter-traction if needed. The edge of the hysterotomy is then grasped and the plane of dissection is carefully developed using a combination of blunt and sharp dissection (Figure 9). If fertility is desired, care should be taken to circumvent the endometrial cavity if at all possible.

When multiple myomectomies are being performed, it is recommended that the minimum number of incisions needed be placed. It is advised that no more than three to four incisions be placed in the uterus [18]. Therefore, multiple leiomyomas should be removed from a single incision if feasible. As the leiomyomas are removed, a strict count should be kept to ensure all specimens are removed at the conclusion of the case. Some surgeons may opt to string the leiomyomas together with suture.

Once the leiomyoma has been enucleated, the hysterotomy is then closed in multiple layers. If the endometrium is breached, the defect should be closed with 3-0 or 4-0 suture. Care should be taken to avoid penetration of the cavity to avoid intracavitary adhesion

formation [33]. Depending on the depth, the myometrium can be closed in one or two layers. The serosa is then closed. A running stitch of barbed suture can be used for the myometrial and serosal layer [18, 33].

Figure 9. Robotic assisted enucleation of a uterine leiomyoma.

Due to concerns for uterine rupture, delivery via cesarean section is recommended for patients who subsequently achieve a viable pregnancy.

Specimen Removal

While leiomyosarcomas are extremely rare, approximately 2-3/1,000 hysterectomies performed for leiomyomas will find an underlying sarcoma [34]. After a highly publicized case involving an undiagnosed leiomyosarcoma that was removed via uncontained, power morcellation, the FDA discouraged the use of the laparoscopic power morecellator during the time of hysterectomy and myomectomy in 2014 [33]. The power morcellators were subsequently taken off the market. This resulted in a transition to contained, hand morcellation of large specimens.

For specimen removal, the GelPOINT access platform (Applied Medical, Rancho Santa Margarita, CA, US) may be placed through a 2-3 cm mini-laparotomy at the umbilicus. The umbilicus is recommended for improved cosmetics. All leiomyomas should be placed inside an FDA-approved endoscopic specimen bag. While smaller leiomyoms may fit through the mini-laparotomy, larger specimens may require contained, hand morcellation. This technique can also be applied for the removal of enlarged uteri.

To perform contained morcellation, it is recommended that the Extracorporeal C-Incision Tissue Extraction (ExCITE) technique be used. The specimen bag is brought up through the incision and opened. A self-retaining wound retractor is then placed inside of the bag. The

specimen is then grasped and a reverse c-shaped incision is made on the specimen with an 11-blade scalpel. Serial c-incisions are made to create a long strip of tissue. Constant upward traction is applied to facilitate rolling of the specimen.

During contained morcellation, pneumoperitoneum should be maintained to keep a safe distance from the underlying bowel. The scalpel should also be kept at an angle to avoid damaging the specimen bag and therefore, placing the patient at risk for seeding.

ENDOMETRIOSIS AND CHRONIC PELVIC PAIN

Endometriosis is defined as the ectopic growth of endometrial glands and stroma. It is most commonly found in the pelvic peritoneum but can be found in the ovaries, rectovaginal septum, ureter, bladder, bowel, pericardium, pleura and previous scar tissue.

Approximately 6-10% of reproductive aged women are affected by endometriosis [36]. In women with infertility and chronic pelvic pain, the prevalence of endometriosis is 38% and 71-87% respectively [36]. Risk factors for endometriosis are early menarche, short menstrual cycles, heavy prolonged cycles and family history of endometriosis [36]. Patients with a decreased risk are those with a higher parity, increased duration of lactation and participation in regular exercise [36].

Pathogenesis of Endometriosis

There are multiple theories on the pathogenesis of endometriosis including Sampson's theory, lymphatic or vascular spread, coelomic metaplasia and induction theory. Retrograde menstruation, also known as Sampson's Theory, is the most commonly accepted theory. However, the presence of endometriosis in ovarian tissue stroma, vulva, pleura and umbilicus (Villars nodule) suggests other mechanisms. Therefore, the pathophysiology of endometriosis is likely multifactorial.

Sampson's theory, also known as the theory of retrograde menstruation, describes dissemination of endometrial tissue into the peritoneal cavity via retrograde menstruation through the fallopian tubes at the time of menses [28]. Baboon models for endometriosis, largely performed by T. M. D'Hooghe et al. have widely supported this theory [37, 38]. However, while the vast majority of women will experience retrograde menstruation as a normal phenomenon of menses, only 6-10% of women have endometriosis.

The theory of lymphatic or vascular spread suggests that endometrial tissue is spread by aberrant lymphatics or vasculature. This is supported by the presence of extra pelvic endometriosis, exclusive retroperitoneal endometriosis and the lymphatic spread of endometrial adenocarcinoma; however, limited data exists on this theory [28].

The theory of coelomic metaplasia hinges on the pluripotential tissue of the parietal peritoneum. It is thought that this tissue undergoes metaplastic transformation into tissue histologically identical to that of normal endometrium. This is supported by the presence of endometriosis in the ovary and in the absence of menstruation—for example, premenarche and postmenopausal women and men treated with estrogen following orchiectomy for prostate cancer [28].

Induction theory suggests that hormonal and biological factors induce differentiation of undifferentiated cells into endometrial tissue. These factors can be either exogenous or directly released from the endometrium. In vitro studies have supported this theory [28].

Clinical Presentation and Work-Up of Endometriosis

While the classic clinical presentation of endometriosis is described as painful menses, the presentation is often more varied and complex. Aside from dysmenorrhea, patients often report chronic pelvic pain, dyspareunia, menorrhagia, infertility and sacral back pain. Endometriosis can also affect the bowels and bladder. As a result, patients may describe perimenstrual tenesmus, diarrhea, constipation, cramping, dyschezia, hematochezia, dysuria, hematuria and dysuria.

In patients with endometriosis, a pelvic exam may reveal tenderness, uterosacral ligament nodularity or an adnexal mass, if an endometrioma is present. Vaginal endometriosis can be found by performing a careful speculum exam (Figure 10). For patients with abdominal wall endometriosis, a nodule is often palpated near the site of a previous surgical incision.

The role of imaging in endometriosis is limited. The vast majority of the lesions are small and will not be present on ultrasound, MRI or CT scan. Therefore, the utility of imaging is in the detection of endometriomas, adenomyosis and nodular extra-pelvic endometriosis. If bladder or colon involvement is suspected, a cystoscopy and colonoscopy should also be performed.

For the definitive diagnosis of endometriosis, the gold standard is histologic confirmation of lesions removed at the time of surgery. Histologic findings consistent with endometriosis are endometrial glands and stroma, with varying amounts of inflammation and fibrosis [36]. Given the small size of most lesions, a laparoscopic approach should be taken.

Figure 10. Nodule of vaginal endometriosis.

Medical Management of Endometriosis

Endometriosis lesions cause an increase in cyclooxygenase-2 activity, resulting in an increase in prostaglandins. They create chronic inflammation via increased active macrophages and inflammatory cytokines [36]. An increased density of nerve fibers can also be seen in these lesions, as nerve growth factor is highly expressed. This accounts for much of the chronic pain symptoms associated with endometriosis. Therefore, NSAIDs are recommended for management of pain. For patients with evidence of long-term nerve damage from the disease, neuromodulators such as gabapentin, pregabalin and amitriptyline can also be utilized.

One of the key components of the development of endometriosis is the overproduction of local estrogen by increased aromatase activity and progesterone resistance [36]. Patients frequently report significant pain with menses as well. Hence, most hormonal options for the management of endometriosis are focused on achieving amenorrhea and decreasing estrogenic effects. Combined oral contraceptive pills, progesterone only options—such as Depo-Provera, Norethindrone and the levonorgestrel-releasing intrauterine device, and gonadotropin releasing hormone agonists can be used to achieve this.

Robotic Assisted Surgical Approach and Management of Endometriosis

Surgery for the management of endometriosis should be used judiciously. As with medical management of endometriosis, surgery is also associated with a significant recurrence rate of pain. A retrospective study by Shakiba et al. showed the reoperation rate for women who underwent an operative laparoscopy for endometriosis at 2-, 5- and 7- years to be 20.6%, 46.7% and 55.4% respectively [39]. Therefore, prior to undergoing any surgery for endometriosis, patients should be well counseled on realistic goals and outcomes.

While biopsy of endometriotic appearing lesions is not required, it is recommended for pathological confirmation of the disease [36]. Discrepancies between the intra-operative appearance of lesions and histology are not uncommon. Endometriosis is classically described as a blue-black, powder-burn lesion; however, the physical appearance of endometriosis can be quite varied. Lesions can appear red, white or vesicular. If the disease has been long standing, there can be evidence of chronic inflammation and scarring. Patients can also develop a frozen pelvis (Figure 11).

Staging for endometriosis is based upon the intra-operative findings. The stage is described as a number I-IV, correlating with minimal, mild, moderate or severe disease [40]. This is determined based on the type, size and location of the lesions of endometriosis, extent of adhesions and presence of posterior cul-de-sac obliteration found at the time of surgery, per the American Society for Reproductive Medicine's guidelines for the classification of endometriosis [36]. However, it is important to keep in mind that the severity of symptoms does not always correlate with the extent of disease found at the time of laparoscopy. Therefore, the intra-operative findings should not sway the post-operative management of endometriosis.

In order to optimize patient outcome, the goal of endometriosis surgery is to completely remove all visible areas of endometriosis, lyse all adhesions, and restore normal pelvic anatomy [41]. If endometriosis of the bowel or bladder is suspected, the respective surgical

subspecialties should be readily available for intra-operative consultation at the time of surgery. The da Vinci Xi system's ability to access any anatomic landmark from virtually every position makes it an optimal surgical platform when anticipating a multi-disciplinary approach to surgery.

Figure 11. A: Classic black powder burn-lesion of endometriosis. B: Red lesions of endometriosis. C: Peritoneal damage due to endometriosis. D: Frozen pelvis of Stage IV endometriosis.

Surgical Approach

Once the abdomen is entered and trocars are placed, care must be taken to systematically evaluate the abdomen and pelvis. All pelvic surfaces and organs should be thoroughly assessed, including the ureteric ridge and infraovarian fossa. It is recommended that the diaphragm, bladder, colon and appendix be assessed for endometriosis as well.

Superficial endometriosis lesions are generally seen on the peritoneal, serosal and ovarian surfaces [40]. The depth perception of the robotic platform is advantageous for identifying superficial lesions as it allows for enhanced visualization of cobblestoning and terrain changes [41]. A study performed by Mosbrucker et al. showed the 3D/HD robotic scope was associated with a 2.36 times likelihood of detecting a confirmed lesion of endometriosis compared to conventional 2D laparoscopy [41]. The use of Firefly fluorescence or narrow band imaging technology can also enhance the visualization of lesions (Figure 12). Once these superficial lesions are found, they can be either excised or ablated.

Deeply infiltrating endometriosis is defined as a nodule of endometriosis measuring >5mm in depth. These lesions are often found along the uterosacral ligaments, posterior cul-de-sac, vagina, bowel, bladder and ureter [40]. These lesions should be completely excised, as complete excision has been shown to decrease pain and the rate of symptomatic recurrence [40, 42]. In addition to being hypervascular, these lesions can be densely adherent, and often near vital organs and structures. The enhanced dexterity of the robotic system allows for more facile and precise dissection of these nodules.

Particularly in stage III and IV endometriosis, dense adhesions of the pelvic organs are frequently encountered. A key component in fertility-sparing, surgical management of

endometriosis is restoration of normal pelvic anatomy. Therefore, adhesiolysis should be undertaken. Surgeons should also be prepared to perform ureterolysis and dissect in the pararectal and paravesicular spaces.

Figure 12. Side by side view of vesicular endometriosis comparing with and without narrow band imaging.

In patients who no longer desire fertility, hysterectomy is a viable option for management, with or without ovarian conservation. The retrospective study performed by Shakiba et al. showed that 23% of patients with ovarian conservation and 8.3% of patients who did not undergo conservation underwent a subsequent surgery for endometriosis by 7-years post-op [39]. The surgery free time between those with and without ovarian conservation was not statistically different for patients between 30-39 years of age [39]. Therefore patients should be counseled extensively regarding the risks and benefits of an oophorectomy.

To delay symptomatic recurrence, it is recommended that some form of hormonal suppression therapy be started in the post-operative period in patients not seeking immediate fertility [40].

Endometrioma

Endometriomas result from the proliferation of endometriotic lesions in the ovary. Due to the collection of blood over time, when ruptured, these cysts release a chocolate brown fluid. Recommendation for removal is varied, with some suggesting removal if the size is >3cm [36]. If surgery on the ovary is undertaken, care should be taken to preserve as much ovarian tissue as possible.

Recurrence rates for endometriomas are quite high, particularly if they are only drained at the time of surgery. It is recommended that the cyst wall be completely excised. If this is not feasible, coagulation of the wall should be attempted; however, this is associated with a higher rate of recurrence of pain compared to excision [36].

Please refer to the section “Surgical Approach to the Adnexal Mass” for details on completing a cystectomy.

Adenomyosis

Adenomyosis is the presence of ectopic endometrial glands and stroma within the myometrium. As a result, myometrial contractility is impaired. Patients can experience abnormal uterine bleeding as well as pelvic pain. Hysterectomy is the standard treatment for

adenomyosis [42]. Symptomatic management for those who desire to retain fertility can be challenging. The levonorgestrel IUD can be utilized in those patients looking to avoid surgery.

If an adenomyoma is found, an adenomyomectomy can be considered. Unlike leiomyomas, adenomyomas do not have a capsule and is often not well demarcated from normal myometrium. The enhanced 3-D visuals of the robotic platform can help to differentiate between normal myometrium and the adenomyoma. The surgical approach and principles for adenomyomectomy mirror that of a myomectomy for leiomyomas.

Please refer to the section on “Robotic Assisted Laparoscopic Myomectomy” for further details.

Endometriosis of the Bowel

5.3-12% of women with endometriosis will have deeply infiltrating endometriosis involving the bowel [43, 44]. Lesions of the rectum and rectosigmoid junction account for 70-93% of intestinal endometriosis (Figure 13) [45]. In addition to the traditional symptoms of endometriosis, patients frequently report deep dyspareunia, non-cyclic pelvic pain, dyschezia and hematochezia. Many patients will also carry the diagnosis of irritable bowel syndrome. If endometriosis of the bowel is found, management with a colorectal surgeon is advised.

Due to scarring and fibrosis, these lesions respond poorly to hormonal management and ultimately will require surgery [45]. Options for management range from surgical excision of the nodule to segmental resection. To aid in this decision, patients should undergo a colonoscopy as well imaging such as an MRI or transvaginal or transrectal ultrasound. Size, depth, extent of the lesion and presence of stenosis are utilized to determine the need for a segmental resection. A nodule >3cm, involvement of the muscularis or >40% involvement of the bowel circumference often favors segmental resection [43–45]. In these instances, excision alone will place the bowel at risk for stenosis.

Figure 13. Endometriosis nodules of the sigmoid colon.

Complications range from anastomotic leakage, fistula formation and obstruction [43]. Surgical management of low rectal lesions is associated with a higher rate of leaks and transient neurogenic bladder dysfunction [44].

Elche, Spain

²Department of Nursery, University Hospital San Juan de Alicante,
Alicante, Spain

ABSTRACT

Obesity is a significant risk factor for surgical site infection. Antibiotic prophylaxis in bariatric procedures has not been adequately evaluated.

The chapter summarizes the recent evidence about microbiology, recommended antibiotics, dosages and other routes of administration in obese and morbidly obese patients undergoing bariatric procedures.

Keywords: antibiotic prophylaxis, surgical site infection

INTRODUCTION

Surgical site infection (SSI) is defined as infection occurring within 30 days after surgery (or within 1 year if an implant is left in place), which may be incisional (superficial or deep) or organ/space [1].

Obesity is considered a risk factor for SSI independently of other comorbidities and, specifically in clean and clean-contaminated abdominal procedures, so antibiotic prophylaxis is always needed in laparoscopic and open bariatric procedures [2-4].

The goal of antimicrobial prophylaxis is to control bacterial burden maintaining antibiotic levels above the minimum inhibitory concentration of the bacteria throughout the procedure. General principles are:

* Corresponding Author's Email: andres.garciam@goumh.umh.es.

- A) Intravenous administration.
- B) Antibiotic: narrower-spectrum agents to cover the typical microorganisms, bactericidal activity, extended half life, good tissue distribution and low adverse effects.
- C) Posology: maximum dose, 30-60 minutes before the start of the procedure with special attention to intraoperative redosing [1, 3].

BARIATRIC SURGERY

Microbiology

The main involved microorganisms in bariatric procedures are grampositive cocci (*Staphylococcus spp.*, *Streptococcus spp.* and, less frequently, *Enterococcus spp.*) and, in the case of gastrointestinal anastomosis, gramnegative bacilli (*Escherichia coli*, *Proteus spp.*, *Klebsiella spp.*) and anaerobes (*Bacteroides spp.*) are included [3, 5].

ANTIBIOTICS

The recommended antibiotic depends on the bariatric procedure. For surgeries above the duodenum, cefazolin and, in patients with β -lactam allergies, vancomycin and gentamicin, clindamycin and gentamicin or levofloxacin are preferred. For surgeries below the duodenum, amoxicillin-clavulanic and, in patients with β -lactam allergies, moxifloxacin, levofloxacin and metronidazole or gentamicin and metronidazole are preferred [1, 3, 6].

DOSAGES

The alteration in body composition in obese patients involves a higher risk of erroneous dosing and, therefore, a possible therapeutic failure or toxicity.

There is a little pharmacokinetic and pharmacodynamic evidence related to the optimal dose in bariatric procedures [3, 7].

The main parameters for doses calculation are:

- a) Body mass index (BMI): $\text{weight (kg)} / \text{height (meters)}^2$.
- b) Ideal weight:
 - Men: $50 + 0.9 \times [\text{height (centimeters)} - 152]$.
 - Women: $45.5 + 0.9 \times [\text{height (centimeters)} - 152]$.
- c) Adjusted weight: $\text{corrective factor} \times (\text{total weight} - \text{ideal weight}) + \text{ideal weight}$.
Corrective factor represents the percentage of excess of weight in which antibiotic is estimated to be distributed and varies between 0.25 – 0.4 [3].

Suggested initial dose and time to redosing for recommended antibiotics would be:

- a) Cefazolin and amoxicillin-clavulanic: 2 gr., with dose repetition if the surgery lasts more than 3-4 hours. There are different studies related to the assessment of the adequate antibiotic prophylaxis. Anlicoara et al. described a higher concentration of cefazolin in adipose tissue with 2 gr preoperative followed by continuous infusion of 1 gr diluted in 250 ml of saline solution, above the minimum inhibitory concentration of the main causal agents of the SSI [8], whereas Chen et al. have reported cefazolin protective levels in serum and adipose tissue with a 2 gr., and they concluded that neither high dose of cefazolin (3-4 gr.) nor intraoperative redosing are necessary [9].
- b) Gentamicin: 5-7 mg/kg of adjusted weight with a corrective factor of 0.47. Dose repetition is not required [3].
- c) Vancomycin: 15 mg/kg of total weight (maximum dose 2 gr.). Dose repetition is not required [3, 10].
- d) Clindamycin: 900-1200 (BMI $\geq$ 50) mg., with dose repetition if the surgery lasts more than 6 hours [1, 2].
- e) Quinolones: maximum doses, levofloxacin 500-750 (BMI $\geq$ 50) mg. and moxifloxacin 800 mg [1, 3].
- f) Metronidazole: 15 mg/kg of total weight. Dose repetition is not required.
- g) Cefoxitin. Brunetti et al. evaluated plasma and adipose tissue concentrations of cefoxitin after preoperative standard dose (2 gr.) in 6 patients undergoing sleeve gastrectomy and they described subtherapeutic concentrations in subcutaneous tissue at the time of closure so they recommend more studies to define the appropriate dosage [11]. Moine et al. described that weight-based dosing regimen (40 mg/kg of total weight) was better than fixed dose, although the desired pharmacodynamic targets were suboptimal in serum and subcutaneous tissue, so more studies are needed [12].
- h) Ertapenem. Borracci et al. evaluated the standard dose of 1 gr of ertapenem in 10 female patients undergoing bariatric surgery and they concluded that it may not provide optimal clinical levels to prevent SSI [13].

OTHER ROUTES OF ADMINISTRATION

The application of topical, subcutaneous and intraperitoneal antibiotics has also been studied.

Peritoneal lavage with antibiotic solution has been used by many surgeons in abdominal surgery to reduce the bacterial load and possibly minimize the risk of SSI [14]. Ruiz-Tovar et al. performed a randomized clinical trial comparing peritoneal lavage with antibiotic solution (gentamicin 240 mg. – clindamycin 600 mg. dissolved in 500 ml. of physiologic saline) versus physiologic saline after laparoscopic sleeve gastrectomy and they described a significant reduction in peritoneal contamination, inflammatory markers, post-operative pain and a shorter length of hospital stay in the group of antibiotic solution. More studies with a higher sample size are needed to obtain significant conclusions about SSI with peritoneal lavage with antibiotic solution [15].

Alexander et al. evaluated the infusion of kanamycin solution 0.1% into the subcutaneous at the time of closure in 837 patients undergoing open bariatric procedures in addition to standard intravenous prophylaxis. SSI developed in subcutaneous tissues of 0.72% of patients and they concluded that prolonged contact with kanamycin solution reduced SSI in the deep subcutaneous space. However, no control group was included in the study, so more studies are needed to evaluate the use of topical solutions and the SSI [16].

Chapter 261

THROMBOEMBOLIC PROPHYLAXIS

Jaime Ruiz-Tovar^{1,*} and Carolina Llaveró²

¹Department of Surgery, Universidad Autónoma de Madrid, Spain

²Department of Surgical Nursery, Sureste Hospital, Madrid, Spain

ABSTRACT

Obesity is associated with an increased risk of thromboembolic events. Venous thromboembolisms are the most common postoperative medical complications after bariatric surgery. Moreover, most bariatric procedures actually are performed by laparoscopic approach, implying an increased intraabdominal pressure during the surgical procedure that may favor the development of thrombus. The incidence of deep vein thrombosis (DVT) after laparoscopic bariatric surgery is about 3%. The prolonged anti-Trendelenburg position is considered the most important risk factor for venous thromboembolisms.

DVT is probably the most easily detected complication associated with venous thromboembolism, as it tends to appear with unilateral pain in the lower limb, associated with gastrocnemius edema and tenderness. DVT alone is not a life-threatening condition, but its main risk is migration of the thrombus and the development of PE.

Therefore, bariatric surgery is considered a high-risk procedure for thromboembolic events. Actual recommendations are to include low molecular weight heparins (LMWH) and compression stockings in the primary prophylaxis of thromboembolic events.

Keywords: bariatric surgery, thromboembolic prophylaxis

INTRODUCTION

According to the World Health Organization (WHO), there are 1.6 billion overweight and 400 million obese people worldwide. Bariatric surgery has demonstrated to be the most effective and sustainable method for the regulation of morbid obesity, superior to both pharmaceutical interventions and combinations of diet and lifestyle regimens. Therefore, the

* Corresponding Author's Email: jruiztovar@gmail.com.

number of bariatric procedures performed, mainly in developed countries, is increasing every year [1, 2].

Obesity itself is associated with an increased risk of thromboembolic events. Moreover, most bariatric procedures are actually performed by a laparoscopic approach, implying an increased intraabdominal pressure during the surgical procedure that may favor the development of thrombus. Therefore, bariatric surgery is considered a high risk procedure for thromboembolic events [3, 4].

MORBID OBESITY AS RISK FACTOR

It has been determined that obesity is associated with a hypercoagulability status. Morbidly obese patients present increased fibrinogen levels that may reach twofold the normal value. It has been proved that venous circulation flow is slower in the infradiaphragmatic territory and especially in the lower limbs. Both facts, associated with disorders in several coagulation factors, favor the appearance of venous thrombosis, thrombophlebitis, and thromboembolic events, mainly pulmonary thromboembolisms (PE), which are the first cause of mortality in obese patients.

Venous stasis and hypercoagulability improve with weight loss, mostly after bariatric surgery. This improvement is achieved several months after the surgical procedure, when an important weight reduction has been obtained. More than 90% of patients undergoing any bariatric procedure present a relevant reduction of their hypercoagulability.

PE is also the most frequent cause of mortality in the immediate postoperative course of any kind of surgery in obese patients. Thus, they are considered as high-risk subjects, requiring intense prophylactic measures (mechanical and pharmacological) [5-7].

Laparoscopic Bariatric Surgery

Venous thromboembolism is the most common postoperative medical complication after bariatric surgery. The incidence of deep vein thrombosis (DVT) after laparoscopic bariatric surgery is about 3% and that of pulmonary embolism (PE) is less than 1%. However, mortality associated with PE is estimated to be between 50% and 75% [8-10].

In laparoscopic abdominal surgery, the increase of intraabdominal pressure by the pneumoperitoneum, the prolonged operation time, and the anti-Trendelenburg position are considered risk factors for venous thromboembolisms. Moreover, hypercapnia induces vasoconstriction. It has been also demonstrated that surgical dissection induces the release of procoagulant cytokines. Other causes of venous thromboembolism after bariatric surgery is dehydration, especially after restrictive procedures, when patients hardly drink [11].

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Venous thromboembolisms are often a challenging issue for the medical staff. DVT is probably the most easily detected complication associated with venous thromboembolism, as

it tends to appear with unilateral pain in the lower limb, associated with gastrocnemius edema and tenderness.

DVT alone is not a life-threatening condition, but its main risk is migration of the thrombus and the development of PE. The gold standard method for the diagnosis of DVT is Doppler ultrasonography (US).

PE usually appears with sudden unexplained dyspnea without any relevant features at the physical examination and on X-ray plain films. Laboratory data may show increased levels of D dimers, which present high sensitivity but low specificity for the suspicion of PE. The gold standard test for the diagnosis is a contrast-enhanced thoracic computed tomography (CT) scan showing a filling defect in the pulmonary arteries or their branches [11].

Antithromboembolic Prophylaxis (Primary Prophylaxis)

Venous thromboembolisms are life-threatening conditions. Several measures, including prophylactic low molecular weight heparins (LMWH) and compressive stockings, are adopted to reduce their incidence. Up to the present there is no consensus about the optimal dosage of LMWH in the antithromboembolic prophylaxis for patients undergoing bariatric surgery. The dosage must be adjusted according to the weight of the patient, implying the need of administration of high preoperative doses.

Intra- and postoperative bleeding is one of the main complications of bariatric surgery. Many surgeons fear these complications and administer lower doses of LMWH than that recommended by most groups (Enoxaparin 0.5 mg/kg/day or Bemiparin 5000 UI/day or Dalteparin 50 UI/kg/day or Nadroparin 4100 UI/day) [12-15]. However, other authors report that this dose is insufficient because these patients are at high risk of developing thrombotic events [16-18].

The postoperative prolongation of prophylaxis is also a debated issue as some authors defend that a prolongation of 5–7 days is enough, whereas others report the need for maintaining it during 1 month, considering laparoscopic bariatric surgery as a high-risk procedure performed in high-risk patients [19-21]. In our opinion, a preoperative dose of 0.5 mg/kg administered 12 h before surgery and maintained postoperatively for 1 month is an adequate scheme for pharmacological antithromboembolic prophylaxis. We also fear intraoperative bleeding, but at these doses, it is not especially relevant in our experience. However, a postoperative thromboembolic event is a life-threatening condition for us that, once established, could be very difficult to manage.

Compression stockings must be maintained during the surgical event and postoperatively until the patient is able to make a proper ambulation [22, 23].

Screening for Asymptomatic Venous Thromboembolism (Secondary Prophylaxis)

As has already been mentioned, venous thromboembolisms are asymptomatic in many cases. In DVT it is especially important to achieve an early diagnosis to avoid the development of life-threatening conditions, such as PE. With this aim, our group performed a prospective observational study of 100 consecutive patients undergoing laparoscopic sleeve

gastrectomy as a bariatric procedure. DVT and porto-spleno-mesenteric vein thrombosis (PSMVT) were investigated 3 months after surgery with Doppler US and contrast-enhanced abdominal CT scan. The results of this study revealed that 2% presented unnoticed DVT and 1% unnoticed PSMVT. All these patients were asymptomatic. According to these results, we concluded that a routine postoperative screening with Doppler US or contrast-enhanced CT seems to be unnecessary [24].

ABSTRACT

Postoperative nausea and vomiting (PONV) are still frequent, despite the continuing investigation and development of new drugs and techniques. These condition contribute to increase hospital costs, delay discharge from the hospital, demand unexpected hospitalizations, and decrease patient satisfaction. Postoperative nausea and vomiting usually develop in the first 24 postoperative hours and can lead to significant morbidity. In abdominal surgeries, the increase in intraabdominal pressure jeopardizes the stitches, increases central venous pressure, and increases the risk of aspiration of gastric contents. Electrolyte imbalances and an increase in intracranial pressure can also be observed. The effort during vomiting increases postoperative pain and autonomous responses.

Laparoscopic gastropplasties are associated with a high incidence of postoperative nausea and vomiting and the number of those procedures has been increasing progressively, hence the need to identify methods to prevent those undesirable events in this patient population.

Multimodal antiemetic prophylaxis has been recommended for patients who have multiple risk factors. Unfortunately, provider compliance with recommended antiemetic prophylaxis protocols is low historically. In bariatric patients, it was observed that those undesirable effects can have an incidence of almost 80% when prophylaxis is not used. Given these results, it would be logical to attempt to further lower the PONV rates. [9]

Keywords: postoperative nausea and vomiting (PONV), risk score, antiemetics

INTRODUCTION

Among the millions of patients undergoing surgery with general anesthesia each year, many suffer from postoperative nausea, vomiting, or both (PONV). Severe nausea can be so draining and debilitating that patients have rated it as more serious than postoperative pain. In obese patients undergoing bariatric surgery, vomiting increases the risk of pulmonary aspiration of gastric contents and suture dehiscence. It may even lead to esophageal rupture, subcutaneous emphysema, and bilateral pneumothoraces. In addition, PONV can delay patient discharge from the postanesthesia care unit (PACU), and it is a leading cause of unexpected hospital admission after surgery. [3]

This chapter has the next goals:

- A. Identify which patients are at risk for PONV: RISK SCORE.
- B. Establish factors that reduce the baseline risks for PONV.
- C. Determine the most effective antiemetic drugs.
- D. Create an algorithm to identify patients at increased risk for PONV and suggest effective prophylactic strategies.
- E. Describe PONV treatment with or without prophylaxis.

PATIENTS AT RISK FOR PONV

In bariatric patients, the most common event for prolonged postanesthesia recovery is PONV. Patients having bariatric surgery have several known risk factors related to PONV, but some of these factors may be only simple associations. [9]. For objective risk assessment, it is recommended to focus on those conditions that independently predict PONV after accounting for other confounding factors. Independent risk factors have been identified.

- *The most likely causes of PONV are anesthesia related: volatile anesthetics, nitrous oxide, and postoperative opioids.*

The effect of volatile anesthetics on PONV is dose-dependent and particularly prominent in the first 2 to 6 hours after surgery. In a study of more than 1100 patients, volatile anesthetics were the single greatest factor affecting the incidence of emesis in the first 2 h after operation, and volatile anesthetic use increased PONV in a dose-dependent manner, irrespective of the choice of the agent. Nitrous oxide may contribute to PONV in several ways. It may act upon the dopamine and opioid receptors in the brain, produce changes in middle ear pressure, and cause bowel distension as it diffuses into closed cavities. [26]

Irrespective of the specific drug given, postoperative opioids also increase the risk for PONV in a dose-dependent manner, and this effect appears to last for as long as opioids are used for pain control in the postoperative period. Opioid analgesia primarily involves central μ , κ , and δ receptors in the rostral anterior cingulate cortex and the brainstem. However, opioid activity at peripheral receptors in the gut inhibits the release of acetylcholine from the mesenteric plexus and stimulates μ receptors, which reduces muscle tone and peristaltic

activity. Consequent delayed gastric emptying and gastric distension activate visceral mechanoreceptors and chemoreceptors, which trigger nausea and vomiting via a serotonergic signalling pathway.

This explains why the incidence of PONV is lower with opioid-free regional anesthesia and anesthesia regimens with reduced opioid consumption through the use of non-opioid analgesics, perioperative alpha-2 agonists, and beta-blockers.

- Despite the triggers mentioned above, many patients do not experience PONV, most likely because the development of PONV also depends on the individual patient's susceptibility. *Patient-specific risk factors for PONV in adults include female sex, a history of PONV and/or motion sickness, nonsmoking status, and young age.*

Female gender is the strongest overall predictor of PONV. An estimated 40% of female surgical patients who receive postoperative opioid analgesics have PONV. The mechanism relating female gender to increased incidence of PONV is yet unknown. The incidence of PONV varies with the phase of the menstrual cycle, but menstrual hormonal fluctuations are unlikely to be responsible for PONV.

A history of PONV, motion sickness, or both indicates an underlying susceptibility to PONV. A genome-wide association study to identify potential genetic markers for susceptibility to PONV found that patients with a history of severe, intractable PONV were more likely to have first-degree relatives with a history of PONV than those with no history of PONV.

The mechanism for the reduced incidence of PONV in smokers compared with non-smokers is also not well understood. One theory suggests that chronic exposure to polycyclic aromatic hydrocarbons in cigarette smoke might induce the cytochrome P450 isoenzymes (CYP2E1) responsible for phase 1 (first pass) metabolism of volatile anesthetics. However, given that only a small percentage of volatile anesthetics gets metabolized (e.g., 0.02% of desflurane), it appears unlikely that liver enzyme induction could account for such wide variation in the incidence of PONV between smokers and non-smokers. Thus, it has been proposed as an explanation that the protective effect of smoking may be due to functional changes in neuroreceptors from chronic exposure to nicotine, and thus nicotine withdrawal rather than nicotine exposure reduces smokers' susceptibility to PONV.

The incidence of PONV generally decreases with age. An underlying mechanism may be the reduced autonomic reflexes with increasing age. However, it should be noted that this is true for adults only, as the incidence of PONV increases with age in children, with a relatively low reported incidence below the age of 3. [8]

Type of surgery is strongly believed to be a risk factor for PONV, yet it is difficult to prove that it is an independent risk factor. Certain types of surgery may be associated with a frequent incidence of PONV (e.g., abdominal surgeries), not because of a specific emetogenic pathway, but could be as a result of a long exposure to general anesthesia and higher doses of opioids.

There is not enough evidence for other commonly believed risk factors as anxiety, menstrual cycle, perioperative fasting, nasogastric tube or supplemental oxygen. [1]

Risk Score

Historically, there have been several problems with the prevention of PONV. First, the efficacy of prophylactic antiemetic interventions in the daily surgical setting is often disappointing. Second, there is no evidence that prophylaxis decreases the likelihood of unanticipated admission. Third, it remained unclear whether prophylaxis of PONV is less cost-effective than treatment of established symptoms. And finally, with prevention strategies, patients who actually do not need any prophylaxis are unnecessarily exposed to a drug, and are thus put at risk of suffering from unnecessary adverse drug reactions.

Antiemetics, like all drugs, carry some risk for adverse effects. These effects range in severity from mild headache to possibly more meaningful QTc prolongations that may rarely be associated with cardiac arrest.

Therefore, a patient's baseline risk for PONV should be objectively assessed using a validated risk score that is based on independent predictors, so the number and choice of prophylactic antiemetics can be titrated against the patient's risk. Even though there is strong evidence for a couple of truly independent risk factors for PONV, none of those risk factors taken alone as a single predictor is clinically sufficient for a risk assessment or to make clinical decisions about the need for prophylactic antiemetics. Therefore, a patient's baseline risk for PONV should be objectively assessed using a validated risk score that is based on these independent predictors. Indeed, use of PONV risk scores has been demonstrated to significantly reduce the institutional rate of PONV. The 2 most commonly used risk scores for inpatients undergoing balanced anesthesia are the Apfel score and the Koivuranta score. [4, 1, 3]

The Apfel simplified risk score is a predictive model, which was developed in European patients undergoing balanced anesthesia. It is based on 4 predictors: female gender, history of PONV and/or motion sickness, nonsmoking status, and use of postoperative opioids. According to this score, the risk factors are each assigned a value of 1. The incidence of PONV with the presence of 0, 1, 2, 3, and 4 risk factors is about 10%, 21%, 39%, 61%, and 79%, respectively. It could be considered patients with 0–1, 2 or 3, and more risk factor as “low,” “medium,” and “high” risk categories, respectively.

Given that several antiemetics are now generic and inexpensive, some experts suggest it may be appropriate to give 1 or 2 antiemetics to all patients. However, this strategy puts the low-risk patients at unnecessary risk for rare but well-described side effects. Although risk scores are an objective approach to assessing the patient's risk for PONV, they are not completely predictive, with sensitivity and specificity of between 65% and 70%. In addition, other clinically relevant aspects should also be taken into consideration by the anesthesia care provider, such as whether vomiting after bariatric surgery would pose a significant medical risk. [3, 4]

REDUCE BASELINE RISKS

Reducing baseline risk factors can significantly decrease the incidence of PONV. Strategies recommended to reduce baseline risk include:

- 1) *Avoidance of general anesthesia by the preferential use of regional anesthesia.*
- 2) *Preferential use of propofol infusions.*
- 3) *Avoidance of nitrous oxide.*
- 4) *Avoidance of volatile anesthetics.*
- 5) *Minimization of perioperative opioids.*
- 6) *Adequate hydration.*

The IMPACT study evaluated 6 strategies to reduce PONV in more than 5000 high-risk patients. They found that a combination of propofol and air/oxygen (total IV anesthesia [TIVA]) had additive effects, reducing PONV risk by approximately 25%. Use of propofol for induction and maintenance of anesthesia decrease the incidence of early PONV (occurring within the first 6 hours).

These findings are supported by 2 meta-analyses demonstrating that avoiding nitrous oxide reduced PONV risk, but only if the baseline risk of vomiting is high. Omitting N₂O does not affect nausea or complete control of emesis. There is evidence showing that volatile anesthetics were the primary cause of early PONV (0–2 hours after surgery), but that they did not have an impact on delayed PONV (2–24 hours after surgery). [5]

Baseline risk for PONV can also be reduced by minimizing postoperative opioids. To achieve satisfactory analgesia without opioids, alternate modalities of pain management may be used. RCTs and meta-analyses showed that multimodal analgesic regimens which decreased the opioid consumption also decreased the incidence of opioid-related nausea and vomiting. These morphine sparing effect could be arised by the use of regional techniques, antiinflammatory drugs, cyclooxygenase-2 inhibitors and low doses of intraoperative ketamine. [7]

Adequate IV fluid hydration is an effective strategy for reducing the baseline risk for PONV. However, there was no difference in efficacy between crystalloids and colloids when similar volumes were used in surgeries associated with minimal fluid shifts.

ANTIEMETIC DRUGS

The etiology of nausea and vomiting is multifactorial and it is related with four types of neurotransmitters: serotonin, dopamine, acetylcholine, and histamine. They modulate the chemoreceptor trigger zone located in the area postrema. Antiemetics are classified according to their action on these receptors and normally affect one of them. Therefore, the use of a single drug might not be adequate and the association of two or more drugs might be necessary to obtain better results. [9]

The recommended pharmacologic antiemetics for PONV prophylaxis in adults include:

- a. *5-Hydroxytryptamine (5-HT₃) Receptor Antagonists* (ondansetron, dolasetron, granisetron, tropisetron, ramosetron, and palonosetron),
- b. *Neurokinin-1 (NK-1) Receptor Antagonists* (aprepitant, casopitant, and rolapitant),
- c. *Corticosteroids* (dexamethasone and methylprednisolone),
- d. *Butyrophenones* (droperidol and haloperidol),
- e. *Antihistamines* (dimenhydrinate and meclizine),
- f. *Anticholinergics* (transdermal scopolamine [TDS]).

Recommendations given are evidence based, and not all the drugs have a Food and Drug Administration (FDA) indication for PONV.

Other proposed strategies were found to be not effective for PONV prophylaxis like music therapy, isopropyl alcohol inhalation, intraoperative gastric decompression, the proton pump inhibitor esomeprazole, ginger root, nicotine patch to nonsmokers, cannabinoids and intraoperative supplemental oxygen. Morindal citrofolin linn (noni fruit) showed effectiveness in reducing early postoperative nausea.

a) 5-HT₃ Receptor Antagonists

Ondansetron is a highly effective antiemetic that has been used successfully for both the prophylaxis and treatment of postoperative nausea and vomiting (PONV) in high-risk surgical patients. [4, 12]

Most of the available research on the 5-HT₃ receptor antagonists involves ondansetron, which has greater antiemetic than antinausea effects. Ondansetron is the “gold standard” compared with other antiemetics. It exerts its actions by inhibiting the release of serotonin by enterochromaffin cells in the stomach; those receptors are found in the termination of afferent fibers that travel in the vagus nerve to the postrema region of the solitary tract nucleus, responsible for emesis. [9]

It has a recommended dose of 4 mg. The effect of the ondansetron 8 mg oral disintegrating tablet is equivalent to the 4 mg IV dose. Ondansetron is as effective as other 5-HT₃s including ramosetron 0.3 mg. It is also as effective as dexamethasone and haloperidol 1 mg IV, with no difference in effect on the QTc interval. However, it is less effective than aprepitant for reducing emesis and palonosetron for the incidence of PONV.

Timing of Administration

Ondansetron, dolasetron, granisetron, and tropisetron are most effective in the prophylaxis of PONV when given at the end of surgery, although some data on dolasetron suggest timing may have little effect on efficacy. Palonosetron is typically given at the start of surgery.

Adverse Effects

The 5-HT₃ receptor antagonists have a favorable side effect profile, and while generally considered equally safe, all except palonosetron affect the QTc interval. In June 2012, the U.S. FDA recommended the dose of ondansetron for chemotherapy-induced nausea and vomiting should not exceed 16 mg in a single dose because of risks of QT prolongation. In December 2012, the FDA notified that the 32 mg single IV dose will no longer be marketed. However, there was no change in the recommended dose of ondansetron 4 mg to prevent PONV. Other adverse effects of Ondansetron are: headache, elevated liver enzymes, and constipation.

b) NK-1 Receptor Antagonists

Aprepitant is an NK-1 receptor antagonist with a 40-hour half-life. In 2 large RCTs, aprepitant (40 and 80 mg per os) was similar to ondansetron in achieving complete response (no vomiting and no use of rescue antiemetic) for 24 hours after surgery. The clinical

experience with the use of aprepitant is still limited, and its role in routine prophylaxis is not established.

Other NK-1 receptor antagonists have not been approved for use.

c) Corticosteroids

The corticosteroid dexamethasone effectively prevents nausea and vomiting in postoperative patients. A prophylactic dose of 4 to 5 mg IV for patients at increased risk for PONV is recommended after anesthesia induction rather than at the end of surgery. Dexamethasone has an effective antiemetic effect throughout the first 24 hours of the postoperative period. On the contrary, if administered at the end of anesthesia, dexamethasone did not provide an effective antiemetic effect during the immediate postoperative period of 0–2 hours. [10, 1]

For PONV prophylaxis, the efficacy of dexamethasone 4 mg IV is similar to ondansetron 4 mg IV and droperidol 1.25 mg IV and each independently reduced PONV risk by approximately 25%.

More recent studies increasingly use the higher dose of dexamethasone 8 mg IV rather than the minimum effective dose of 4 to 5 mg. Preoperative dexamethasone 8 mg enhances the postdischarge quality of recovery in addition to reducing nausea, pain, and fatigue. Dexamethasone also has dose-dependent effects on quality of recovery. At 24 hours, patients receiving dexamethasone 0.1 vs 0.05 mg/kg required less opioid and reported less nausea, sore throat, muscle pain, and difficulty falling asleep.

Adverse Effects

Data on safety of perioperative dexamethasone are inconclusive. In most studies, a single dose of perioperative dexamethasone does not appear to increase the risk of wound infection. However, it has been reported that intraoperative dexamethasone 4 to 8 mg may confer an increased risk of postoperative infection. In addition, some studies showed significant increases in blood glucose that occur 6 to 12 hours postoperatively in normal subjects, those with impaired glucose tolerance, and type 2 diabetic and obese surgical patients who receive dexamethasone 8 mg. In view of this evidence, use of dexamethasone in labile diabetic patients is relatively contraindicated.

Methylprednisolone 40 mg IV is effective for the prevention of late PONV. There is no evidence to suggest that the adverse effect of methylprednisolone is any different from dexamethasone.

d) Butyrophenones

Butyrophenones produce central nervous system (CNS) depression, and they are potent antiemetics. Droperidol produces its action centrally at sites where dopamine, norepinephrine, and serotonin act. As a principal mechanism it has been suggested that droperidol may occupy GABA receptors at the postsynaptic membrane; this may reduce synaptic transmission and result in a buildup of dopamine in the intersynaptic cleft. A subsequent imbalance in dopamine and acetylcholine is thought to occur, which results in an alteration of normal transmission of signals in the CNS, as, for instance, in the emetic centre in the chemoreceptor trigger zone.

Droperidol has been used as an antiemetic in perioperative medicine for almost 40 yr. Extensive clinical experience with a drug is no guarantor for that drug to be clinically really useful. There was some evidence that the timing of administration of prophylactic droperidol may have an impact on its early antiemetic efficacy, but not there after. From a pharmacokinetic point of view it seems to be reasonable to administer a prophylactic antiemetic intervention shortly before the patient awakes and possibly needs the antiemetic protection. Droperidol is most effective when administered at the end of surgery. The antinausea effect is not dose-dependent, is more pronounced than the anti-vomiting effect, and is short-lived. Sedation and drowsiness are dose-dependent, extrapyramidal symptoms are rare, and there is a protective effect against headache. [11]

Prophylactic doses of droperidol 0.625 to 1.25 mg IV are effective for the prevention of PONV.

Adverse Effects

Droperidol and other, older antiemetic drugs have been repeatedly discredited because of their apparent increased risk of potentially major adverse effects. The situation with droperidol is different, because this drug is clearly antiemetic in the doses used in clinical practice. Its antinausea effect, for instance, is likely to be the best currently available. Thus, it may be worthwhile to balance the estimates of the antiemetic efficacy of droperidol against its estimates for harm. Extrapyramidal symptoms is a major adverse reaction of drugs acting at the dopamine receptor. There was a lack of data to test dose-responsiveness; it can only be speculated that lower doses of droperidol would decrease the risk of extrapyramidal reactions. Visual disturbances, urinary retention, and oculogyric crisis have been described. The clinical relevance of these events and their relation to droperidol, however, is unclear.

It has been known for a long time that droperidol, as a CNS depressant, produces a drowsy and placid subject who tends to fall into a sleep from which he can be readily aroused. Indeed, droperidol increased the likelihood of sedation and drowsiness; an obvious dose response could be described.

There was strong evidence for a protective effect of droperidol against postoperative headache. This puts into question general statements on the increased risk of toxicity with droperidol. We do not know if there is a relationship between an increased risk of sedation and the anti-headache effect. The favourable effect on headache is yet another reason why droperidol should be combined with a 5-HT₃receptor antagonist, since 5-HT₃ receptor antagonists increase the risk of headache.

Many physicians stopped using droperidol in 2001 due to the FDA “black box” restrictions on its use. However, the droperidol doses used for the management of PONV are extremely low, and it is believed that at these dosing levels, droperidol is unlikely to be associated with significant cardiovascular events. Several studies have documented the equal QTc effects of droperidol versus ondansetron. Due to this warning, droperidol is not the first choice for PONV prophylaxis in many countries.

Haloperidol has antiemetic properties when used in low doses and has been investigated as an alternative to droperidol. At doses much lower than those used to treat psychiatric disorders (0.5 to 2 mg IM or IV), haloperidol effectively reduced PONV risk. At these doses, sedation does not occur, and cardiac arrhythmias are not reported.

Haloperidol carries a risk of QTc prolongation in its label and is not recommended as first-line therapy. Haloperidol 1 mg IM or IV may be regarded as an alternative to droperidol.

Of potential interest, haloperidol may be given IM or orally. Its efficacy can be increased when combined with other antiemetics (dexamethasone or ondansetron). It should be noted that the use of haloperidol as an antiemetic or the IV route of administration is not an FDA-approved indication.

e) Antihistamines

Dimenhydrinate is an antihistamine with antiemetic effects. The recommended dose is 1 mg/kg IV. Data from placebo-controlled trials suggest that its antiemetic efficacy may be similar to the 5-HT₃ receptor antagonists, dexamethasone, and droperidol. There is not enough data available to establish the optimal timing and dose response for dimenhydrinate administration or its side effect profile. Direct comparisons with other antiemetic drugs are lacking.

f) Anticholinergics

A systematic review of TDS showed that it is useful as an adjunct to other antiemetic therapies. The patch effectively prevented nausea and vomiting postoperatively up to 24 hours. It can be applied the evening before surgery or 2 to 4 hours before the start of anesthesia due to its 2- to 4-hour onset of effect.

Adverse effects associated with TDS are generally mild, the most common being visual disturbances, dry mouth, and dizziness. Dry mouth occurs mostly on the first day of use. A higher prevalence of visual disturbances can be observed at 24 to 48 hours. TDS is useful for control of nausea in the setting of PCA.

g) Other Antiemetics

Phenothiazines

Perphenazine is a phenothiazine derivative that has been used for the prevention of PONV at doses between 2.5 mg to 5 mg IV or IM. A systematic review from 6 RCTs demonstrated a relative risk reduction for PONV with a recommended dose of 5 mg IV, with no increase in sedation and drowsiness when compared with placebo.

Metoclopramide

Metoclopramide is a weak antiemetic and at a dose of 10 mg is not effective in reducing the incidence of nausea and vomiting. Despite having been used extensively in anesthetic practice, is not antiemetic in the recommended doses in the perioperative period. [11]

Metoclopramide's dose-response curve was evaluated in relation to other antiemetics. Metoclopramide high doses (25-50 mgr) are neccesaty to obtain an effect similar to ondansetron 4 mg. Dyskinesia or extrapyramidal symptoms can increase with increasing metoclopramide doses.

Propofol

Propofol is a sedative-hypnotic widely used for induction and maintenance of general anesthesia and monitored anesthesia care sedation with local or regional anesthesia. Numerous studies have demonstrated propofol has antiemetic properties. The median plasma propofol concentration associated with an antiemetic response was much lower (343 ng/ mL) than the concentration ranges associated with general anesthesia (3–6 mcg/mL) or sedation

(1–3 mcg/mL), allowing propofol to have antiemetic properties in the subhypnotic dose range.

Propofol used as part of TIVA is recommended to reduce baseline risk for PONV. The benefit of a small dose propofol infusion (bolus of 1 mg/kg followed by an infusion at 20 mcg/kg/min), either by itself or in combination with other antiemetics, has been shown to reduce PONV. Propofol, in small doses (20 mg as needed), can be used for rescue therapy for patients in the direct care environment, for example, PACU, and has been found as effective as ondansetron. However, the antiemetic effect with low doses of propofol is likely brief.

- *Alpha2-Agonists*: In a meta-analysis, perioperative systemic alpha2-adrenoceptor agonists (clonidine and dexmedetomidine) showed a significant albeit weak and short-lived antinausea effect. This effect may be explained by direct antiemetic properties of alpha2-agonists or its opioid-sparing effect, although the biological basis remains obscure.
- *Mirtazapine* is a noradrenergic and specific serotonergic antidepressant. Prophylactic mirtazapine delays the onset of PONV. Mirtazapine plus dexamethasone reduces the incidence of late PONV by >50% compared with dexamethasone alone. Less rescue medication is needed with the combination of antiemetics.
- *Gabapentin* doses of 600 mg per os given 2 hours before surgery effectively decreases PONV. Given 1 hour before surgery, gabapentin 800 mg per os is as effective as dexamethasone 8 mg IV, and the combination is better than either drug alone.
- *Midazolam* decreases nausea and vomiting compared with placebo. Midazolam 2 mg when administered 30 minutes before the end of surgery was as effective as ondansetron 4 mg. Midazolam 1 mg/h was as effective as a subhypnotic dose of propofol 1 mg/kg/h when given at the end of surgery. Midazolam 2 mg given 30 minutes before end of surgery decreased PONV more effectively than midazolam for premedication.

ANTIEMETIC PROPHYLAXIS ALGORITHM

There are at least four major receptor systems involved in the etiology of postoperative nausea and vomiting (PONV). The concept of combination antiemetic therapy was first introduced in 1988 by Parikh in chemotherapy induced vomiting. Its success prompted similar research in the field of PONV. There are enough evidence published comparing the relative efficacy of combination vs single agent antiemetic prophylaxis. [13] All these studies support the combination therapy for PONV. Apfel et al. demonstrated that the effects of antiemetics acting on different receptors are additive.

The efficacy of an intervention thus depends critically on patients' baseline risk. Interestingly, there were no significant interactions among the antiemetic interventions, among the anesthetic interventions, or among the antiemetics and the anesthetics. The resulting relative risk of nausea and vomiting associated with a combination of interventions can thus be directly calculated as the product of the individual relative risks. As a consequence, the absolute risk reduction provided by a second or third intervention is less

than that provided by the initial intervention (irrespective of which combination is chosen). Multiple interventions should thus generally be reserved for patients at high risk for postoperative nausea and vomiting or those in whom nausea and vomiting would be especially dangerous.

Because each tested antiemetic agent and the use of total intravenous anesthesia reduced the relative risk of nausea and vomiting to a similar extent, the logical sequence is to use the least expensive or safest intervention first. Additional interventions that cost more or that are associated with a greater chance of adverse effects will further reduce the absolute risk, but to a lesser extent than will the initial intervention. Combining prophylactic interventions therefore markedly increases costs and the likelihood of adverse effects while providing progressively less additional absolute benefit.

Management techniques such as total intravenous anesthesia cannot be used once postoperative nausea and vomiting have begun. Dexamethasone, similarly, prevents postoperative nausea and vomiting only when given near the beginning of surgery, probably by reducing surgery-induced inflammation. Moreover, “rescue” treatments are ineffective when the same drug has already been used prophylactically. [4, 11]

Adults at moderate risk for PONV should receive combination therapy with drugs from different classes as the efficacy is optimized when a combination of drugs with different mechanisms of action are administered.

The 5-HT₃ antagonists have better antiemetic than antinausea efficacy but are associated with headache. These drugs can be used in combination with droperidol, which has greater antinausea efficacy and is associated with lower risk of headache. The 5-HT₃ antagonists can also be effectively combined with dexamethasone. Combination therapy regimens using ondansetron with either droperidol or dexamethasone are most widely studied.

To know about dose-responsiveness is important for two reasons. First, when larger doses are not much more efficacious than smaller doses, the smaller doses are likely to be more cost-effective. Second, smaller doses may be less harmful. [14] It has been suggested that when used as combination therapy, dexamethasone doses should not exceed 10 mg IV, droperidol doses should not exceed 1 mg IV, and ondansetron doses in adults should not exceed 4 mg and can be much lower. Multiple studies confirm the effectiveness of combination therapy with dexamethasone.

Patient-Controlled Analgesia

Approximately one-third of patients who are treated with opioids for postoperative pain will have nausea and vomiting. Droperidol effectively reduced the risk of nausea and vomiting, when given concomitantly with morphine in a PCA device. Other studies evaluating the effects of various other antiemetics on PCA-related PONV showed a benefit (Ramosetron, Ondansetron, TDS).

Nonpharmacologic Prophylaxis

A meta-analysis of 40 articles including more than 4500 subjects concluded that P6 stimulation with different acupuncture modalities reduces nausea, vomiting, and the need for

rescue antiemetics compared with sham stimulation. The efficacy of P6 stimulation is similar to that of prophylactic antiemetics such as ondansetron, droperidol, metoclopramide, cyclizine, and prochlorperazine. In subgroup analysis, there was no difference in effectiveness in adults compared with children or invasive versus noninvasive modalities for P6 stimulation. The timing of transcutaneous acupoint electrical stimulation does not impact PONV, with similar reductions being achieved with stimulation initiated before or after induction of anesthesia. Neuromuscular stimulation over the median nerve also reduces the incidence of PONV in the early postoperative period, particularly when tetanic stimulation is used.

Other Methods and Alternative Therapies

Low-dose naloxone (0.25 mcg/kg/h), reduced nausea and vomiting and decreased the need for rescue medication compared with placebo. Lower infusion rates were also effective in reducing the incidence of nausea and sedation induced by tramadol infusion.

PONV TREATMENT

When nausea and vomiting occur postoperatively, treatment should be administered with an antiemetic from a pharmacologic class that is different from the prophylactic drug initially given. If no prophylaxis was given, the recommended treatment is a low-dose 5-HT₃ antagonist. The 5-HT₃ antagonists are the only drugs that have been adequately studied for the treatment of existing PONV. The doses of 5-HT₃ antagonists used for treatment are smaller than those used for prophylaxis: ondansetron 1.0 mg; granisetron 0.1 mg; and tropisetron 0.5 mg. All the 5-HT₃ antagonists, except palonosetron (that has not been studied for PONV treatment), are equally antiemetic for the treatment of established PONV.

Alternative treatments for established PONV include dexamethasone (2 to 4 mg IV), droperidol, (0.625 mg IV), or promethazine (6.25 to 12.5 mg IV). Propofol, 20 mg as needed, can be considered for rescue therapy in patients still in the PACU and is as effective as ondansetron. However, the antiemetic effect with low doses of propofol is probably brief.

Repeating the medication given for PONV prophylaxis within the first 6 hours after the initial dose conferred no additional benefit. During the first 4 postoperative hours, patients who failed PONV prophylaxis with ondansetron 4 mg did not respond either to a second administration of ondansetron 4 mg or to crossover with granisetron 0.1 or 1 mg.

If more than 6 hours has elapsed, it may be possible to achieve some effect with a second dose of a 5-HT₃ antagonist or butyrophenone (droperidol or haloperidol), but this has not been demonstrated in clinical trials and should only be attempted if triple therapy has been used for prophylaxis and if no alternatives are available for rescue that have not been used for prophylaxis. Readministration of longer-acting drugs, for example, dexamethasone, TDS, aprepitant, and palonosetron is not recommended. The attempt at rescue should be initiated when the patient complains of PONV and, at the same time, an evaluation should be performed to exclude an inciting medication or mechanical factor for nausea and/or vomiting.

Contributing factors might include an opioid PCA, blood draining down the throat, or an abdominal obstruction. [1]

Figure 1. PONV prophylaxis.

KEY POINTS

1. Postoperative nausea and vomiting (PONV) are among the most common adverse events after bariatric surgery. Compared with other postoperative complications, PONV is of minor medical importance; it almost never kills, and it never becomes chronic. However, PONV may be very distressing for patients and workload for nursing staff is increased. Intractable PONV creates considerable extra costs for health care systems.
2. A patient's baseline risk for PONV should be objectively assessed using a validated risk score (Apfel Score) that is based on independent predictors: female gender, history of PONV and/or motion sickness, nonsmoking status, and use of postoperative opioids.
3. PONV prophylaxis should be considered for patients at moderate to high risk for PONV. Among the interventions considered, a reduction in baseline risk factors and

use of nonpharmacologic therapy are least likely to cause adverse events. Depending on the level of risk, prophylaxis should be initiated with monotherapy or combination therapy using multiple interventions.

4. Antiemetic combinations are recommended for patients at moderate and high risk for PONV. Combining interventions has an additive effect in risk reduction.
5. The safety of antiemetics is well established considering the huge amount of clinical data available and their summary in valid meta-analyses. Limited adverse effects have been associated with the use of minimum effective doses of most recommended antiemetics.
6. When rescue therapy is required, the antiemetic should be chosen from a different therapeutic class than the drugs used for prophylaxis, and potentially one with a different mode of administration. If PONV occurs within 6 hours postoperatively, patients should not receive a repeat dose of the prophylactic antiemetic. An emetic episode more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis (except dexamethasone, TDS, aprepitant, and palonosetron).

Chapter 263

NUTRITIONAL PROPHYLAXIS: WEIGHT LOSS FOR THE REDUCTION OF SURGICAL RISK

Irene Portero Larragueta

Rey Juan Carlos Hospital, Móstoles, Madrid

ABSTRACT

Surgical risk depends directly on comorbidities, age, and body mass index. Obesity is not only associated with a wide range of comorbidities, it has important implications for them as well.

In fact, some of these comorbidities could be easily controlled or even cured just by losing weight.

In this scenario, it seems logical that weight loss before bariatric surgery would reduce surgical risk in morbidly obese patients. This logic thinking has been demonstrated by many scientific studies and reviews.

Many techniques and diets have been tested over the last decade to achieve this goal.

Nowadays low calorie diets months before surgery, along with very low calorie diets 4 to 8 weeks prior to surgery seem to be the most effective approach.

Keywords: risk, comorbidities, preoperative

INTRODUCTION

Every surgical procedure has possible complications. The risk of having these complications in the perioperative period is what we call surgical risk. Many scores have been developed to predict postoperative outcomes, and have proven their efficacy over the past decade. One thing they have all in common is the importance of comorbidities to define surgical risk.

Obesity has implications for, and is associated with an important number of comorbidities, such as type-2 diabetes, cardiovascular and respiratory diseases and, even, some types of cancer.

Due to the unsatisfactory results with medical interventions, the number of bariatric surgeries has increased dramatically since 2000. In this time, surgical procedures have been improved with minimally invasive laparoscopic surgery and very short recovery times. This, along with the good results achieved (in terms of maintenance of weight loss, and improvement or resolution of associated diseases), have led to an increasing number of high-risk and older candidates to bariatric surgery.

SURGICAL RISK IN MORBID OBESE PATIENTS

There is little evidence to suggest that being moderate overweight would increase surgical risk in young adults, but morbidity and mortality increases dramatically if BMI > 30. The risk of premature death doubles in individuals with BMI > 35. Sudden unexplained death is 13 times more likely in morbidity obese women compared with non-obese.

Overweight men participating in the Framingham study had a mortality rate 3.9 times greater than the normal weight group. Morbidity obese patients are at a much greater risk of mortality from diabetes, cardiorespiratory and cerebrovascular disorders, as well as some types of cancer.

As has been said before, surgical risk depends directly on coexisting diseases. These are the most common comorbidities associated with morbid obesity, and the ones responsible for mayor postoperative complications at the same time:

1. Respiratory Comorbidities

Respiratory physiopathology of morbid obesity patients: lung compliance and functional residual capacity decline exponentially with increasing BMI, witch impairs the capacity to tolerate periods of apnea. Total respiratory resistance is increased, leading to an increase of work of breathing. Oxygen consumption and carbon dioxide production are increased due to a higher metabolic activity of the excess fat and the increased workload on supportive tissues. In exercise, oxygen consumption rises more sharply than in non-obese individuals, which implies respiratory muscle inefficiency. Defects in gas exchange are usually only modest, but this deteriorates dramatically on induction of anesthesia.

Obstructive sleep apnea: 5-10% of morbidity obese patients have OSA, and obesity is the principal risk factor of it. Recurrent and untreated apnea leads to hypoxemia and hypercapnia, which leads to polycythemia and increased risk of heart and cerebrovascular disease; and in extreme cases, right ventricular failure.

Obesity hypoventilation syndrome: it is a long term consequence of untreated OSA, in which the acid-base disorder remains present during the day.

Anesthetic Implications

Induction of anesthesia can be complicated in a patient with an increased risk of difficult or failed intubation. Mask ventilation is likely to be difficult because of upper airway obstruction and reduced pulmonary compliance. In this case, periods of hypoxemia and hypercapnia may increase pulmonary resistance and precipitate right heart failure.

Pulmonary complications are more common in the obese patient, and they are more sensitive to the effects of sedative drugs, which can increase their respiratory impairment in the postoperative period.

The hazards of OSA may be at their worst some days after surgery; with the obvious implications for the duration of postoperative oximetry and oxygen therapy.

2. Cardiovascular Comorbidities

Cardiovascular pathophysiology: total blood volume is increased with most of this extra volume distributed to the fat organ. There is a linear relationship between cardiac weight and body weight, as a consequence of dilation and eccentric hypertrophy of the left ventricle that results in reduced compliance and left ventricle diastolic function. Morbidity obese tolerate badly exercise with an increase in cardiac output being achieved by increasing heart rate without an increase in stroke volume or ejection fraction.

Hypertension: up to 60% of the obese patients suffer mild to moderate hypertension, and up to 10%, severe hypertension. The exact mechanism for hypertension in the obese is not known. Weight loss has been shown to reduce hypertension.

Ischemic heart disease: obesity is an independent risk factor for ischemic heart disease.

Cardiac arrhythmias: may be precipitated by: hypoxia, hypercapnia, coronary artery disease, OSA.

Anesthetic Implications

In order to avoid perioperative complications, the patient should have a detailed cardiovascular examination. Morbidity obese patients often have very limited activity and would appear to be asymptomatic even when they have significant cardiovascular disease. Hypertension and signs of heart failure must be investigated and, if found, correctly treated.

3. Diabetes Mellitus

Obesity is an important independent risk factor for type 2 diabetes. All obese patients undergoing bariatric surgery should be investigated for the presence of high blood glucose levels, and if needed, correctly treated. Uncontrolled high blood glucose levels increases wound infection and myocardial infarction risks.

4. Thromboembolic Disease

The risk of deep-vein thrombosis and pulmonary embolism of obese patients undergoing abdominal surgery (non-malignant) is twice the risk of non-obese patients in similar circumstances. It is the commonest complication after bariatric surgery, and pulmonary embolism remains the first mortality cause.

Many factors contribute to the increased risk: prolonged immobilization, polycythemia, increased abdominal pressure, cardiac failure and decrease of fibrinolytic activity.

Measures to prevent venous thromboembolism are mandatory.

Surgical Implications

Morbid obesity is an anesthetic challenge, but it is also associated with some surgical difficulties. Creation of and maintenance of pneumoperitoneum is particularly difficult, due to wall thickness; which leads to a poor visualization of the surgical field.

Other factors, such as hepatomegaly and intraabdominal fat tissue, could compromise surgical technique.

All of these challenges, could mean a longer surgery and, in some cases, the need of open field surgery.

WEIGHT LOSS REDUCES SURGICAL RISKS

The growing number of high-risk patients referred for bariatric surgery has stimulated investigators to expand preoperative assessment programs to attempt to identify surgical risk factors and to prepare patients better for surgery.

Studies have shown that high risk patients face much higher surgical risks than the morbidity and mortality rates described in recent literature. Optimal preparation for high-risk individuals with significant comorbid medical problems remains controversial. Various modalities that possibly decrease risk, including preoperative weight loss, intragastric balloon placement, and staging procedures, have been described.

It appears only logic that physiologic improvements associated with preoperative weight loss would reduce the rate of postoperative complications, which affect length of stay. Numerous reports have confirmed the beneficial effects of even limited weight loss on comorbid medical conditions, such as hypertension, diabetes mellitus, degree of visceral fat, liver size, thromboembolism predisposition, and severity of sleep apnea.

In fact, short-term modest weight loss has been shown to improve cardiometabolic parameters, thereby positively affecting the multiple medical problems.

For example, deep vein thrombosis complicated with pulmonary embolism, is the first cause of mortality in patients undergoing bariatric surgery; thus, improvements in blood coagulopathy and fibrinolysis and an increase in antithrombin III may be an important factor in reducing hospital lengths of stay. Morbidity obese patients with hepatomegaly from fat and glycogen infiltration can undergo increased operating room time and morbidity owing to the inability to retract the liver adequately and increased vascularity. Modest weight loss of just 5% to 10% has been shown to significantly reduce apneic episodes and improve gas exchange.

There is conflicting data in literature as to the true effect of a preoperative weight loss regimen on postoperative complications after bariatric surgery. In 2011, a systematic review concluded that “little evidence is available to support or refute the routine use of preoperative weight reduction in bariatric surgery”. This was also true regarding its effects on perioperative morbidity and postoperative complications. One main reason for the conflicting results might be the heterogeneity of study protocols and the relatively small number of included patients in most studies.

Given the low rates of major complications and mortality after bariatric surgery nowadays (3 and < 0.3% respectively), it is very difficult to find statistically significant differences in the studies. But what we do know is that this morbid-mortality is associated with three factors: male gender, older patients, and higher BMI; being this last one the only factor we can change.

Recent studies and reviews over the past five years give us now enough evidence to strongly recommend preoperative weight loss in all patients undergoing bariatric surgery.

In fact, although some of the complications are reduced in patients with low and medium-high BMI, there is a decrease in the relative risk of all complications in relation to the degree of preoperative weight loss in patients within the highest BMI range.

Reduced technical complexity after preoperative weight loss might be one possible explanation for the effect on postoperative complications. Numerous studies have demonstrated that a two weeks' low or very low calorie diets regimen reduce liver and visceral fat volume with improved visibility and access to the hiatal region.

Early complications such as infections and anastomotic leakage are also reduced. The most plausible explanation for the effects might be related to the fact that patients exposed to pre-operative VLCD could be expected to have a better glucose control in the postoperative period. It is amply demonstrated that a period of hypocaloric nutrition in obese, insulin-resistant subjects will improve insulin sensitivity, mainly due to depletion of glycogen stores and increased glucose uptake. Therefore, patients with improved insulin sensitivity before operation are likely to have better glucose control postoperatively, which has been convincingly demonstrated to be associated with improved outcome after surgery. This is in particular regarding infectious complications.

It seems that approximately 10% of total weight loss is to be recommended to achieve a more pronounced effect compared with a modest preoperative weight loss in the range of 5%. Moreover, patients in the higher range of BMI could be expected to benefit more from preoperative weight loss compared with patients with a less pronounced degree of obesity.

PREOPERATIVE NUTRITIONAL MANAGEMENT

The dramatic change to the bariatric surgery patient's digestive system after surgery warrants education and training prior to surgery. The first step in this process is the preoperative evaluation.

Medical history, laboratory tests and potentially psychiatric assessment and treatment are the major components of the assessment.

The patient's eating behaviour and weight history is an important part of the evaluation. Obtaining an overall view of the patient's nutrition history is important in determining potential barriers to a successful surgical outcome. Identifying these barriers may allow for planning and treatment protocols that increase the likelihood that those patients will achieve clinically significant weight loss post-surgery.

Surgical candidates should be seen by a registered dietitian or other nutrition expert, who will assess the patient's current diet and nutrition knowledge, and also provide education for the postoperative period.

The baseline lab levels can help to differentiate between complications, deficiencies due to the surgery, noncompliance with supplement regimen or pre-existing deficiencies.

In addition to the standard laboratory assessments, other social and demographic factors that could impact the patient's ability to comply with the guidelines should be assessed. As has been shown with many health behaviours, living in an environment that is supportive of positive changes is predictive of success in making changes.

Some of these factors may include ability to afford supplements, high-protein foods, access to food recommended, etc. Assessment of the impact of the patient's socioeconomic status on their surgical outcome is also an important factor to consider in the preoperative phase, especially because socioeconomic problems are prevalent in the bariatric surgery population.

Preoperative Diet

We should divide the preoperative period in two phases:

1. Early Phase

It begins at the very first time the patient is decided to enter a bariatric surgery protocol; and it would be extended throughout all preoperative assessments, tests, visits and preparations.

Morbidity obese patients have tried a very large number and different types of diets, supervised or not by physicians. And have lost and gain weight several times, making very hard for them to really compromise with any nutritional treatment.

At this early stage, a not very restrictive low calorie diet must be initiated (1200-1500kcal/day). Patient should be talk into all the beneficial effects of weight loss before surgery. It must be explained that the ultimate purpose of this diet is a slow weight loss in order to reduce surgical risks and complications. We are looking for an 8% reduction in body weight in 4-6 months.

Besides the primary goal of reducing surgical risks, adherence to nutritional treatment can help the surgeon choose the optimal surgical technique.

There are four types of diet attending to their composition:

Low energy diet: 800-1500kcal/day, balanced (10-15% protein, 50-65% carbohydrates and 25-35% fat). A rapid weight loss can be achieved, but it is usually rapidly regain due to lack of treatment adherence.

Low carbohydrate diet: < 30% carbohydrates, and > 40% fat. Weight loss is fast because of both fat intake and own fat tissue lipolysis. This diet improves insulin resistance, but is associated with and increased LDL-cholesterol levels. They show an important weight loss in 6 months, but it is regained in less than 12 months.

Low fat diet: fat restriction should be the first approach, due to its energetic value. A Cochrane review shows that the sole fat restriction does not lead to a higher weight loss than any other type of diet, concluding that what matters is the energy restriction.

High protein diet: protein is the most satiating nutrient, making the energy intake in this diet very low. On the other hand, cholesterol and uric acid increases because of the increase of animal fats.

Actual scientific evidence recommends a balanced low energy diet, not very restrictive in order to maintain treatment adherence.

It is also important a correct meal planning, dividing daily intake in 5 to 6 meals, reducing fasting periods.

2. Immediate Preoperative Period

Between 2 to 8 weeks prior to surgery, with the aim to obtain a 5-10% of weight loss to reduce surgical risks and facilitate surgical technique as has been exposed.

The very low calorie diet at this phase can be achieved only by a very restrictive diet, by substituting meals with specially designed very low-calorie formulas or by a combination of the two of those approaches, each of them with advantages and disadvantages:

Diet: very low calorie diet means a 450-800kcal/day intake. They are cheap, but difficult to assume. Morbid obese patients are used to large energy intakes, and they are usually not able to stick to them.

Formulas: the very low calorie diet (600kcal/day) is achieved from commercially available specialities in different forms (sachets for smoothies or soup 200kcal each). They have a very tight composition, high protein (50g of high biological value protein), with 13.5 grams of fat and 67.5 grams of carbohydrates, plus vitamins and trace elements. Daily intake of two litres of water is recommended, because its main side effect is constipation. Treatment duration longer than 8 to 10 weeks of is not recommended unless the supervision of an endocrinologist, to monitor both liver and kidney function.

Some studies have shown higher rates in weight loss leading to a mayor risk reduction.

The principal challenge of this diet is the treatment adherence, which can be difficult to some patients, due to the lack of variety in flavours or textures.

This is why some groups support the combination of the two approaches.

Other strategies: The use of an intragastric balloon before surgery has been studied especially in super obese patients (Body mass index above 50 and even 60kg/m²). For its placement it is required an upper gastrointestinal endoscopy under sedation or general anaesthesia, which has to be repeated for its withdrawal, six months after its placement. There are some contraindications to its use as the presence of ulcerative disease or previous gastric surgery. Complications occurred in 10% (desuflation, migration, vomiting) requiring sometimes the early withdrawal before reaching its target. Nowadays it is not recommended.

ABSTRACT

In recent years, the prevalence of morbid obesity treated with bariatric surgery has increased rapidly. Surgery has been demonstrated to be the most effective method to achieve long-term sustained weight loss in the morbidly obese with resolution of most co-morbidities. Some studies indicated a high prevalence of gallstone disease of 10–20% in the general population in industrialized nations. However, only 1–5% of the patients will progress to a symptomatic disease necessitating a cholecystectomy. The prevalence of cholelithiasis, symptomatic or not, is directly correlated to the body mass index (BMI).

In patients after bariatric surgery, the incidence of gallstones or sludge is clearly higher compared to the overall population, ranging from 28 to 71%. These can cause serious problems such as acute cholecystitis, choledocholithiasis and pancreatitis.

Rapid weight loss and altered gallbladder function increase the risk of biliary stone formation. Therefore, the surgical technique chosen in each patient may play an important role in the formation of postoperative cholelithiasis in the medium or long term.

INTRODUCTION

In recent years, the prevalence of morbid obesity treated with bariatric surgery has increased rapidly [1]. Cholelithiasis is not uncommon after weight-reduction surgery. This phenomenon was observed and reported in the early 1990s among patients with rapid weight loss [2, 3].

The incidence of cholelithiasis that has been detected with the ultrasound (US) was reported at 45% in the obese population. Moreover, the prevalence of gallbladder disease is nearly 2-fold higher than that which had been detected within the US when evaluated by gross and histologic examination after cholecystectomy [4]. Obese individuals have a higher prevalence of not only cholelithiasis but also complications like cholecystitis, obstructive jaundice, and pancreatitis when compared with the nonobese population [5]. Despite such high incidence, to perform a cholecystectomy for asymptomatic gallbladder disease in obese patients is not routinely recommended because it can lead to higher morbidity [6].

While the risk of gallstone formation increases 8-fold in patients with BMI >40kg/m² [7], it also increases 5-fold in patients who underwent bariatric surgery compared with normal population [8].

Bariatric surgery causes rapid weight loss and cholelithiasis is common after surgery, with a high incidence within the first 12 months following the procedure. There are many factors associated with the development of gallstones, but the most important are female sex, age >40 years old, and a fast weight loss (losing more than 1.5 kg weekly) [9, 10]. Also, hyper saturation of bile with cholesterol, decreased gallbladder contractility for division of hepatic branch of the vagus nerve, increased levels of mucin that promote the precipitation of crystals contribute to gallstone formation [4, 11].

There is not a clear consensus for the management of gallbladder pathology associated with bariatric surgery patients, especially in asymptomatic cases. There is a wide variety of treatments, such as "preventive" preoperative, prophylactic concomitant or postoperative cholecystectomy. Other options include medical (ursodeoxycholic acid) and conservative (observational) management.

SURGICAL TECHNIQUE AND CHOLELITHIASIS

The question: "What bariatric procedure increases the risk of cholelithiasis and/or choledocholithiasis?" has promoted several studies and it was concluded that the main component that leads to the formation of gallstones was the rapid loss of weight, mainly in the first 6 months, regardless of the technique chosen [12].

In malabsorptive procedures, such as laparoscopic Roux-en-Y gastric bypass (LRYGB), cholelithiasis develops due to changes in the composition of bile, with increases in the calcium and mucin contents leading to the formation of supersaturated or lithogenic bile that crystalizes, deposits, and eventually forms cholesterol gallstones [13]. However, since laparoscopic sleeve gastrectomy (LSG) is a purely restrictive procedure with an intact bowel transit and entero-endocrine system, the details of the mechanism of cholelithiasis development after LSG remain unclear. It was assumed that the division of the lesser omentum during bariatric procedures may cause inadvertent injury to the hepatic branch of the

left vagus nerve, which controls the gallbladder motility [14, 15]; motility dysfunction can thus supervene, resulting in stasis of bile and subsequently cholelithiasis.

Cholelithiasis expected to be less common after LSG or laparoscopic gastric banding (LGB) than LRYGB, because the nutrients continue to follow the normal gastrointestinal tractus [16, 17]. Nevertheless, it was reported no difference in gallstone formation between LSG and LRYGB [16]. Likewise, the highest frequency of cholelithiasis was reported as 71% in patients who underwent LRYGB [18]. Controversially, only 3-16% of these patients turn into symptomatic cases [19-21]. In another retrospective analyze of 1397 bariatric surgery patients (32-month mean follow-up), the incidence of post-bariatric surgery development of cholelithiasis was 10.53% (8.42% for LSG, 13.4% for LRYGB, and 12.7% for mini gastric bypass) and the highest incidence of symptomatic cholelithiasis requiring surgery was detected in LRYGB group (4.54%) [20].

PROPHYLACTIC CONCOMITANT CHOLECYSTECTOMY

Concomitant cholecystectomy (CC) during open bariatric surgery was a common practice at the beginning. The rate of CC has decreased with the development of laparoscopic surgery and most surgeons abstained from CC [22, 23].

Today, there is no consensus on the management of the gallbladder at the time of bariatric surgery. Some authors CC due to probability of postoperative complications and long hospitalization [7]. Controversially, some also reported decreasing rate of postoperative complications and hospitalization time after CC in patients with bypass surgery.

Studies about gallbladder pathologies with the comparison of bariatric procedures give conflicting results. Tsirlina et al. reported a 3-fold increase in cholecystectomy incidence after LRYGB when compared to LSG (10.6 vs. 3.5%) [24]. On the other hand, it was reported that the frequency of symptomatic gallstones after LRYGB and LSG was not significantly different (6.1 vs. 5.7%) [25].

As a result, management of asymptomatic gallbladder stones for LSG and LRYGB should be different.

LRYGB

LRYGB is currently the standard bariatric procedure. The gallbladder management during LRYGB is controversial. Three different approaches have been proposed: first, prophylactic CC in all obese patients undergoing LRYGB [26-28]; second, a selective approach, based on which cholecystectomy is only performed in the presence of gall stones [10, 29, 30] or biliary symptoms [31-33]; third, a wait and see approach, based on which no CC is performed and patients receive prophylactic medication against biliary disease like ursodeoxycholic acid [34, 35].

The latest Bariatric Surgery Guidelines suggest that patients undergoing LGBP also undergo prophylactic cholecystectomy (with a positive US) to prevent gallbladder complications (grade B).

In a meta-analysis based on 13 studies including 6,048 patients provides profound evidence that a prophylactic CC during LRYGB should be avoided in patients without cholelithiasis and exclusively be performed in patients with symptomatic biliary disease. Only 6.8% of the patients without CC during LRYGB progress to symptomatic disease requiring a cholecystectomy. One of the reasons to routinely perform a CC with LRYGB is the concern of later severe biliary complications such as choledocholithiasis or biliary pancreatitis, particularly since endoscopic retrograde cholangiopancreatography (ERCP) is difficult if not impossible to perform after LRYGB. However, the existing data for the general population in industrialized nations indicate that the majority of patients rarely develop complications without first having at least one previous episode of biliary colic [36-39]. Therefore, choledocholithiasis and biliary pancreatitis does certainly not justify a CC as a routine procedure during LRYGB for obese patients. More importantly, however, the CC increased the overall perioperative complication rate by 1.1% (6.2% with CC versus 5.1% without CC).

One meta-analysis provides compelling evidence that prophylactic cholecystectomy in the absence of biliary disease at the time of LRYGB should be avoided. The risk to develop choledocholithiasis or biliary pancreatitis is very low in patients without undergoing a CC during LRYGB.

LSG

There is a paucity of data regarding preoperative evidence of gallstones, incidence of cholelithiasis with concomitant complications, and gallstone formation after LSG. There are only a few studies comparing bariatric procedures concerning gallbladder disease, but the majority of the patients had been performed LRYGB in these studies [4, 12, 17]. Although the incidence of symptomatic gallstones requiring cholecystectomy after LSG was reported as 0.9–7.5%, in two different studies [40, 41], there is insufficient evidence about patient selection for CC, and prophylactic cholecystectomy has never been recommended during LSG.

LSG does not include any bypassed intestinal segment and therefore does not affect the entero-hepatic circulation so endoscopic treatment of bile duct stones would be easier when needed.

Despite CC being reported as safe during LSG, the largest study, with 180 patients, includes intraoperative bile duct injuries with a ratio of 1.1% [42]. Although this ratio can be considered as acceptable, management of bile duct injuries will be more complicated in an obese patient especially in the early postoperative period of bariatric surgery, and even mortality can occur. Additionally, CC prolongs the operative time and may need additional trocars for optimal access.

Today, it is suggested only observation for asymptomatic gallbladder stones for several reasons. First, cholecystectomy in obese patients may be technically challenging due to body habitus and high intra-abdominal pressure [43]. Second, conventional trocar placement of bariatric surgery and cholecystectomy are different, and this may cause visual and procedural difficulties. Third, the anatomy after LSG allows endoscopic management of bile duct stones when needed. Finally, obesity is reported as a risk factor for conversion to open surgery and bile duct injuries [44, 45].

PROPHYLACTIC URSODEOXYCHOLIC ACID THERAPY

Ursodeoxycholic acid (UDCA) is generally used to dissolve gallstones in patients who do not want surgery as the first treatment option and is also indicated in patients with a high risk of cholecystectomy. UDCA is a bile acid and normally it is produced by the body that is stored in the gallbladder. UDCA acts by inhibiting cholesterol secretion in bile, thereby preventing the supersaturation of bile and cholesterol stone formation.

In literature, UDCA use has been supported after bariatric surgery, especially within the first 6 months after surgery for preventing gallstone formation.

Analysis of different dosages has suggested that 300–600mg/day significantly reduces gallstone formation and can be used in patients after bariatric surgery without associated cholecystectomy (grade A). A recent meta-analysis of 5 randomized controlled trials involving 521 patients found that the rate of gallbladder disease/ gallstone formation was significantly lower in patients receiving postoperative ursodiol (8.8 vs. 27.7%; $p = 0.01$). Most of the benefits of such management have been observed within the first 6 months; longer follow-up found no difference in the incidence of de novo gallbladder disease [46]. Because of the heterogeneity of available studies, it has not been clearly established whether this treatment affected the rates of symptomatic disease and emergency cholecystectomy [47].

Another concern is related to the side effects of ursodeoxycholic acid, including diarrhea, skin rash, and decompensation of previous liver diseases [48], which can result in lower patient compliance [10].

Chapter 265

PROPHYLACTIC MEASURES TO REDUCE STAPLE LINE LEAKS AND BLEEDING

*Irene Ortega-Vázquez**

Infanta Sofía University Hospital, European University of Madrid
San Sebastian de los Reyes, Madrid, Spain

ABSTRACT

Background: Laparoscopic gastric sleeve (LGS) is a safe bariatric procedure, growing in popularity due to its technical simplicity and good weight loss outcomes. Bleeds and staple line leak are the most common complications. The postoperative staple line leak does not adversely impact the weight loss and resolution of comorbidities. However, this complication can result in prolonged hospitalization, increased morbidity, sepsis, multi-organ failure and even death. We perform a systematic review to identify patient-factors and surgical strategies that may decrease leak and bleeds after LSG.

Results: Causes of leak are classified as mechanical, technical and ischemic causes. Identified patient-related risk factors are high BMI, ASA, hypertension and degenerative joint disease. The possible contribution of NSAIDs requires further investigation.

Essential surgical technique recommendations include: use a bougie size ≥ 40 Fr; use appropriate cartridge colors from antrum to fundus; follow a proper staple line, with a wide berth around bougie at the incisura angularis; stay away from the angle of His at least 1 cm; check the bleeding from the staple line and avoid 1-stage revisional sleeve concomitant with band removal in high risk patients.

Controversy exists regarding efficacy of staple line reinforcement, surgeons should selectively use those tools until this matter is clarified.

Routine intraoperative methylene blue test is not effective in preventing or predicting postoperative staple line leak.

Conclusions: Laparoscopic gastric sleeve can be performed with low postoperative morbidity and mortality. Standardization of the technique can contribute to decrease postoperative leak rate.

Keywords: sleeve gastrectomy, leak, bleeding, buttressing, oversewing

INTRODUCTION

The laparoscopic gastric sleeve (LSG) was first described by Hess and coworkers [1] in 1998. It was initially conceived as a restrictive component of the biliopancreatic diversion with duodenal switch (BPD-DS) for high-risk patients. After observing marked weight loss with LSG the procedure was eventually adopted as a step approach in the laparoscopic era. As such, it was adopted as the first step for super morbidly obese patients followed by laparoscopic BPD-DS or a laparoscopic Roux-en-Y gastric bypass (LRYGB) [2, 3, 4].

Subsequently, LSG was studied as a definitive operation, recognized as a safe and effective primary metabolic/bariatric surgical operation by the American Society for Metabolic and Bariatric Surgery and the American College of Surgeons [5, 6, 7]. Currently, LSG represents the most common metabolic and bariatric procedure in the USA, accounting for 42% of these operations [8]. LSG has been associated with 57.6% mean excess weight loss (EWL) at 1 year and 70.1% (EWL) at 3 years, superior to restrictive procedures and comparable to malabsorptive-restrictive and primarily malabsorptive procedures over the intermediate term [4].

One of the most attractive aspects of LSG is its relatively procedural “simplicity” [3]. The current procedure involves a stapled mostly vertical transection of the stomach and removal of the left gastric fundus body and proximal left antrum to create a tubular alimentary channel along the stomach’s lesser curvature [4]. Food restriction, early satiety, decrease production on GLP-1 and PYY-36 have been associated changes after LSG [9, 10].

It offers an immediate restriction without need for postoperative adjustments, and no foreign body implanted. It has the advantages of preserving gastrointestinal continuity and the absence of an enteric anastomosis, minimizing nutritional and mineral deficiencies and avoiding dumping syndrome, internal hernias and related complications [3, 4, 7, 11].

In short- and mid- term follow-up, LSG has the lowest procedure-related morbidity compared with RYGB and LAGB [4]. Staple line leaks, bleeding, and strictures are the commonly reported complications following LSG. Bleeding from the staple line can occur in 1-2% patients after LSG, although it is usually less serious than a staple line leak, which implies a long hospital stay, delayed recovery and is the leading cause of death after LSG [12]. Nevertheless, the development of a leakage does not adversely impact the weight loss and resolution of comorbidities in the mid-term [13].

Based on the data of 12799 LSG, the International Sleeve Gastrectomy Expert Panel Consensus Statement 2011, established a leak rate of 1.06%, but the leak rate can vary between 1% and 3% for primary procedure and more than 10% in revision procedures [7].

PATHOGENESIS

Staple line leakage is the most dreadful complication after LSG. This complication is often highly clinically significant and can result in prolonged hospitalization, increased morbidity, sepsis, multiorgan failure, and even death.

Causes of leak are classified as mechanical, technical and ischemic factors [13].

Tobacco use, steroid and medical immunosuppression, supermorbidity, obesity, NSAID use, diabetes, malnutrition, Crohn's disease have been associated with increased rates of gastric leak. We should encourage the patient to modify risk factors.

Leaks are more common among cases requiring blood transfusion (26.2% versus 1.08%, $P = .0031$), higher BMI, higher ASA-stage, longer operating times, when cases were converted to open surgery and revisional surgery [13].

Stapler-related problems or tissue ischemia may lead to impaired tissue healing and dehiscence of the staple line if higher intraluminal pressures are reached. Leaks do to ischemia usually occur around postoperative days 5 to 7, when the healing is between the inflammatory and fibrotic phases, whereas more leaks occur in the first 48 hours, which suggests an additional mechanical cause [14].

Although the technique has wide-spread among bariatric surgeons; there is significant intraoperative variation in technique that makes comparison of results difficult. This heterogeneity may be a significant factor in complication rate, as well as surgical team experience [7, 14, 15].

Outcomes for bariatric surgery have dramatically improved in the past decade and the leak rate after LSG has been decreasing as experience with the technique has increased. The leak rate in Germany significantly decreased over time and since 2010, the leak rate is constantly $< 2\%$ [13]. It has been recently published that surgeons who performed 43 or more cases per year had a leak rate $< 1\%$.

We will perform a literature review and discuss several prophylactic measures and pitfalls to avoid in order to minimize staple line bleeding and leakage.

PROPHYLACTIC MEASURES

1. Bougie Size

There is an increasing trend to use narrower bougies or to begin the division of the stomach closer to the pylorus to presumably reduce the risk of long-term weight regain. Debate exists whether the creation of a tighter sleeve (i.e., smaller) has a higher leak and stenosis rate at the expense of more weight loss¹⁶. This is presumably related to an increase in intraluminal pressure.

However, although weight loss is less rapid for those with bougie size > 40 Fr, the weight loss continued, resulting in similar weight loss in three years. Utilizing bougie ≥ 40 Fr. may decrease leak without impacting % EWL up to 3 years [16, 17].

2. Distance from the Pylorus

The evaluation of Spanish registry data found that beginning the gastrectomy close to the pylorus resulted in better weight loss [18]. Other authors prefer to begin the resection more than 4 cm away from the pylorus, with the aim of preserving the gastric antrum, decreasing intraluminal pressure and improving gastric emptying (and potentially decrease leak) [19, 20].

The meta-analysis published by Parikh suggests that distance to the pylorus does not affect leak rate or weight loss. The report from the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program found that distance from the pylorus had no impact on leaks or bleeds, but showed an increase in weight loss with larger distances [8].

3. Stapling

Gastric wall thickness has been reported to vary, it is thick in the antrum (3.1mm), moderate in the body (2.4mm) and thin in the fundus (1.7mm) [14, 21]. It is not appropriate to use staples with closed height less than 1.5mm on any part of the sleeve (blue) [7].

There has been a movement toward using appropriate staple height for the different components of the sleeve gastrectomy, that is, moving towards a higher staple height for the antrum and thicker stomach, in revisions and when buttress material is used (not less than green, this would be a 2.0mm staple height). The height of the buttress decreases the actual height of the staple and a longer staple height should be considered for safe and proper closure [2, 7, 17, 19].

Stapling at the incisura angularis and the angle of Hiss are crucial steps which should be attempted carefully.

Narrowing the sleeve too much at the incisura angularis may contribute to create leaks at the gastroesophageal junction after LSG. It is advisable to maintain a wide berth around bougie at the curve of incisura [17, 20, 22].

Most leaks (89%) are located proximal [14]. Special care should be applied to limit the posterior dissection at the proximal stomach, preserving the posterior attachments and blood supply in the cardia region. While firing the proximal linear stapler, it is essential to angle the stapler to the left, more than 15mm away from the true gastroesophageal junction [7, 22].

4. Reinforcement of the Staple Line

Reinforcement has been proposed as a method for preventing leaks and bleeding after LSG [7, 16, 19, 23].

Several tools have been proposed to reinforce the staple line and prevent or decrease the staple line leak: oversewing, absorbable synthetic buttress material, bovine pericardium, thrombix matrix and fibrin glue (Tissel, Baxter Corp.) [13, 19, 23].

There has been an increasing trend to use buttressing material along the staple line, although this remains controversial. Earlier studies have reported decreased bleeding with the use of buttressing material such as Bioabsorbable Seamguard and a decreased postoperative morbidity. However several studies have shown no clear benefit of staple line reinforcement.

In the analysis of 241 leaks from 15,576 LSG at the German Bariatric Surgery Registry, oversewing the staple line was associated with the lowest risk of death [13] and was superior to staple line buttressing and no reinforcement.

The use of both, oversewing and buttressing, resulted in the highest leak rate. This finding was also reported in the publication from the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program including 189,477 sleeve gastrectomies [8].

In contrast, Choi [24] reviewed 1335 obese subjects that had undergone LSG and found that reinforcement decreased the risk of a leak without difference between oversewing and buttressing techniques. Interestingly, oversewing seemed to increase the risk of a staple line hemorrhage.

In 2015, Shikora [25] issued a meta-analysis comparing four different reinforcement methods (no reinforcement, oversewing, biocompatible glycolide copolymer and bovine pericardium). Reinforcement was associated with significantly less bleeding and leak rate. The better outcomes were achieved with bovine pericardial buttress.

On the other hand, Gagner [4] published another systematic review comparing the same four reinforcement methods and reported that the leak rate was lower using the absorbable buttressing material.

Despite the fact that literature about staple line reinforcement has contradictory results on leak rates, it definitely minimizes staple line hemorrhage [7, 26]. While the effect of reinforcement on staple line leak remains unclear, it should be used selectively according to surgeon preferences and patient risk.

Independently of the method of reinforcement, another simple gesture suggested by other authors is the apposition of omentum to rest in proximity to the completed staple line [22].

5. Check for Intraoperative Bleeding

Bleeding from staple line can also occur after LSG, in 1 to 2% of patients [12].

Staple line bleeding is considered a direct predisposing factor for leakage after LSG. Hematoma over the suture line affects its vascularity and vitality. It is generally agreed to check carefully staple line for intraoperative bleeding [17].

Recently an observation was made that routine elevation of systolic blood pressure (SBP) to 140 mmHg at the end of stomach resection and oversewing the staple line minimized hemorrhagic complications. Elevation of SBP allowed better identification of intraoperative bleeding [27].

6. Blood Pressure and NSAIDs

A recently published study has found that obese patients with preexisting hypertension and degenerative joint disease have a significant higher risk of postoperative staple line leak [13].

The authors indicate that there is a mayor use of non-steroidal anti-inflammatory drugs (NSAIDs) in these patients. They speculated that NAIDS gastrointestinal toxicity could interfere with staple line healing and suggest discontinuation of NSAIDs prior to surgery or high dose proton pump inhibitor therapy postoperatively [13].

Staple line bleeding is considered a direct predisposing factor for leakage after LSG. Hematoma, over the suture line affects its vascularity and integrity. The regular use of NSAIDs may increase the risk of postoperative bleeding [13]. Nevertheless, further investigation is required to determine the role of NSAIDs in staple line leakage before any recommendation can be made.

Hypertension, especially when not adequately controlled with medication, is a known marker for cardiovascular disease which may deteriorate local blood supply and thus, may increase the risk of staple line disruption [13]. Other authors suggest that hypertension is a surrogate marker for central obesity, which makes the procedure technically more difficult, therefore increasing the postoperative complication rate.

The question about blood pressure and a risk of bleeding in postoperative period should be raised. One study [28] did not show the association between hemorrhagic complications after LSG and high blood pressure levels in postoperative period.

Hypertensive disease should be evaluated and treated pre-operatively in bariatric patients, and close monitorization of blood pressure during the postoperative course should be ensured [13, 22].

7. Intraoperative Leak Testing

Although it is commonly performed, several studies have concluded that intraoperative methylene blue test has no correlation with leak due to laparoscopic sleeve gastrectomy and is not predictive of the later development of staple line leak [29, 30, 31].

Leak tests require the use of nasogastric or orogastric tubes to deliver high pressure dye and there are reported instances of these tubes causing perforations. In fact, Stroh [30] and Bingham [31] postulated that leak testing may increase the risk of postoperative leak.

Other studies have suggested that intra-operative leak test can be negative even when there is a proven leak on CT in patients taken back to theatre, questioning the sensitivity of this test in the first instance [32].

Methylene blue testing has no role in predicting post-operative anastomotic or staple line leak and negative leak test should not be taken as false reassurance of staple line or anastomotic integrity in patients whose post-operative course deviates from the norm [33].

In addition, whilst methylene blue has a reasonable safety profile and is used widely in a host of surgical techniques, it is known to have caused anaphylaxis.

We can conclude that there is no role for its routine use in primary bariatric surgery. Discontinuation of this practice would reduce risk of anaphylaxis, cost, and intra-operative time [33].

8. Revisional Surgery

Conversion of adjustable gastric band to laparoscopic sleeve gastrectomy is feasible with low morbidity and mortality, but multiple reports have indicated higher morbidity and staple line leaks when this is performed as a single-stage procedure [11, 12].

It seems reasonable to consider stage revisional procedure in high risk patients.

CONCLUSION

Pathogenesis of leakage after LSG can be attributed to mechanical, technical or ischemic causes. Many factors can predispose to leakage after LSG which are either technically related

or patient related. Awareness of these predisposing factors and technical tips may decrease the incidence of postoperative leakage.

Within this review, we analyze factors promoting leak and provide technical recommendations to avoid leak after LSG based on the available evidence and expert consensus which encompasses: to use a bougie size ≥ 40 Fr; to use appropriate cartridge colors from antrum to fundus; to follow a proper staple line, with a wide berth around bougie at the incisura angularis; to stay away from the angle of His at least 1 cm; to check the bleeding from the staple line and to avoid 1-stage revisional sleeves concomitant with band removal in high risk patients.

Distance from the pylorus has no impact on leaks or bleeds but increasing distance can impact adversely on weight loss.

Controversy exists regarding efficacy of staple line reinforcement; surgeons should selectively use those tools until this matter is clarified.

Further investigation is required to establish the contribution of high blood pressure and NSAIDs to both bleeding and staple line leak complications.

Routine intraoperative methylene blue test has not proved to be effective in preventing or predicting postoperative staple line leak and should be abandoned.

Chapter 266

POSTOPERATIVE ILEUS PROPHYLAXIS: ENHANCED RECOVERY AFTER SURGERY (ERAS)

Pablo Royo-Dachary* and Helen Almeida-Ponce

Department of Surgery, University of Zaragoza, Zaragoza, Spain

ABSTRACT

Postoperative ileus is a common complication following abdominal surgery. Although ileus per se does not endanger the patient's life, it does lengthen the hospital stay, produces a considerable increase in resources and greatly worsens the patient's well-being. It is one of the pillars on which the ERAS (enhanced recovery after surgery) protocols are centred, together with pain control and correct preoperative optimization. Its etiological mechanism is multifactorial, so to achieve a correct prevention we must know which is the pathophysiology that leads to postoperative ileus and act at different levels to minimize its incidence. Many postoperative measures have been proposed to prevent the appearance of postoperative ileus, some of them without a clear demonstrated benefit. Throughout the next chapter we will review the current evidence regarding these measures.

Keywords: postoperative ileus, prophylaxis, ERAS

INTRODUCTION

A correct working of the digestive system requires a good intestinal propulsive function. The gut has a basic structural organization that includes distinct muscle layers. Intestinal movements are divided into propulsive and mixing ones, and are regulated by multiple nervous and hormonal feedback mechanisms.

Although the manipulation produced during abdominal surgery has traditionally been associated with a decrease in these movements during the postoperative period, not all

* Corresponding Author's Email: proyo@unizar.es.

segments in the gastrointestinal tract are equally affected. Although ileus classically refers to dysmotility of the small bowel, postoperative ileus can selectively affect the stomach, small intestine or the colon, each with a different mechanism and clinical presentation, and each managed differently.

Gastroparesis refers to abnormal gastric motility, which results in delaying of gastric emptying. It is usually associated with medical conditions, as diabetes, but can also occur after abdominal surgery. The stomach recovers a normal activity 24-48 hours after surgery.

Colonic ileus is often seen in elderly patients and usually is related to bedridden patients. It can take up to 3-5 days for the colon to recover a normal function after surgery.

In the case of the small intestine, the movements of mixing and propulsion are simultaneous, although is the abolishment of the propulsion movements that will cause the situation of intestinal ileus. Usually it recovers a normal activity several hours after surgery.

Enhanced recovery after surgery (ERAS) protocols have an evidence based approach to this condition focusing on its prevention by selecting the most adequate techniques for surgery, anaesthesia and other perioperative measures for each patient.

BOWEL PHYSIOLOGY

Propulsion movements can be initiated at any point of the intestine, and cause peristaltic waves that propel the chyme in an anal direction with a velocity of 0.5 to 2 cm/sec (the velocity is higher in the proximal than in the distal intestine). These waves usually cease at 3-5 cm, and rarely span more than 10 cm. All these factors make the speed of the chyme in the intestine about 1cm/minute, so in physiological situations, it takes 3 to 5 hours for the chyme to reach from the pylorus to the ileocecal valve.

When it reaches the ileocecal valve, the intestinal contents can be blocked by it for hours, until a new meal triggers the *gastroileal reflex*, which forces the passage of the chyme into the caecum.

Bowel Innervation

The enteric nervous system is the most complex subdivision of the peripheral nervous system. Two different nerve plexus will form a complex neural network that functions independently of the central nervous system and extends from the esophagus to the internal anal sphincter. Two main components are the myenteric plexus of Auerbach (located between the longitudinal and circular muscle layers) and the Meissner plexus (of submucosal location). The myenteric plexus regulates the contraction and relaxation of the muscle fibers that cause peristaltic movements, while the submucosal plexus is responsible for providing the intestinal lumen sensors, regulating gastrointestinal blood flow and controlling cellular function and secretion of epithelial cells.

In addition to neurons, this enteric nervous system also has enteric glial cells and interstitial Cajal cells. Glial cells form a barrier around the capillaries similar to the blood-brain barrier, while interstitial Cajal cells, that share characteristics of nerve and muscle cells,

act as intestinal pacemakers. They generate and transmit electrical activity that controls smooth muscle function, generating peristaltic movements.

With aging, this enteric nervous system suffers a decrease in neuronal cells, resulting in a dysmotility that clinically manifests itself as constipation, incontinence or defecation alterations. Some pathological conditions associated with obesity, such as diabetes or vascular diseases, can accelerate or simulate this aging process, causing a basal situation of intestinal dysmotility.

The extrinsic nervous system is responsible for modulating the function of the enteric nervous system, and comprises the parasympathetic fibers of the vagus and sacral nerves, which produce excitatory response of smooth muscle fibers and sphincter relaxation, and the sympathetic fibers of the thoracolumbar nervous system, which produces the opposite effect. Sympathetic innervation comes from the solar plexus, a ganglionic ensemble comprising the celiac node, the upper mesenteric nodes, and the aorticorenal nodes, located around the origin of the celiac trunk. These lymph nodes receive nerve afferences from the major (T6-T9), minor (T10-T12), and the inconstant lower (T12) splanchnic thoracic nerves. The efferent branches innervate the digestive tract through the celiac plexus (coronary-stomachic, hepatic and splenic), upper mesenteric plexus and lower mesenteric plexus. The parasympathetic innervation of the vagus nerve regulates up to the splenic angle of the colon, while the innervation of the descending colon, sigma and rectum will come from the sacral parasympathetic.

Nervous and Hormonal Signs

Peristalsis of the small intestine increases after meals due to the *gastroenteric reflex*, triggered by the distension of the stomach and led by the myenteric plexus from the stomach to the rest of the small intestine.

There are also hormonal factors, such as gastrin, cholecystokinin, insulin and serotonin, which stimulate intestinal motility and are secreted at different stages of food digestion. Secretin and glucagon inhibit bowel motility.

The role of ghrelin, whose main function is to regulate appetite, is being widely studied in the bariatric patient. One of its functions is promoting gastric emptying and intestinal motility. This is secreted mainly in gastric fundus and liver cells, so the removal of the gastric fundus, within the different techniques of bariatric surgery, results in a decrease of circulating ghrelin and an abolition of this stimulus. A drastic decrease in this hormone has been found after a vertical gastrectomy, while after gastric bypass and biliopancreatic bypass, a less marked decrease has been found.

Fasting Peristalsis

When eating, the stimulating effect of food controls intestinal movements, but during fasting periods, a special pattern of activity called *motor-migratory complex* occurs. It has three different patterns of motility: neuromuscular rest (phase 1), irregular contractions that vary in amplitude and intensity (phase 2), and uninterrupted contractions of propagation

(phase 3). This motor pattern is under the control of the enteric nervous system and is independent of extrinsic control.

POSTOPERATIVE ILEUS

Ileus is defined clinically as: mechanical, dynamic or adynamic obstruction of the bowel due to failure of the smooth muscle to contract, in absence of mechanical obstruction, occurring during the first postoperative days. It was classically considered to be a physiological and almost mandatory response after abdominal surgery. This alteration of motility was considered to last between 0 and 24 hours for the small intestine, 24 to 48 hours for the stomach, and from 48 to 72 hours for the large intestine, therefore it was only considered pathological when appearing beyond third postoperative day. Today this physiological dysmotility is being discussed, as it seems to be much shorter than previously thought. Prolonged postoperative ileus diagnosis is actually considered when two or more of the following signs or symptoms are present: nausea or vomiting, inability to tolerate oral diet over 24 h, absence of flatus over 24 h, distension, radiologic confirmation occurring on or after day 4 postoperatively without prior resolution of physiological postoperative ileus.

Disparity of criteria for its definition has been the main difficulty for the study of postoperative ileus. While some authors have used solid diet tolerance as an endpoint for their studies, others have considered the elapsed time to first deposition or first flatus, making the different studies carried out incomparable.

It is sometimes difficult to separate postoperative ileus from postoperative nausea and vomiting, a multifactorial postoperative complication that shares many of the characteristics and physiopathology of postoperative ileus. Nausea and vomiting usually occur in the first 24 hours after surgery and are closely related to the anesthesia performed. They require a correct preoperative risk assessment and prophylaxis with antiemetics accordingly with it. Apfel's assessment scale is currently the most widely used, due to its simplicity and usefulness, for the assessment of preoperative risk, and the routine use of its prophylaxis has been validated in multiple studies.

POSTOPERATIVE ILEUM PHYSIOPATHOLOGY

After surgery, mechanisms that affect the normal functioning of the intestinal movement will be put in motion, causing gastrointestinal dysmotility. Some of these mechanisms are as follows:

Inflammation

Intestinal manipulation and surgical aggression trigger an inflammatory response in the intestine. This inflammatory response is not limited to the manipulated segment, but spreads throughout the entire intestine, and not manipulated areas of intestine may be affected.

Studies in animals have shown that manipulation degree is related to leucocyte infiltration of the muscular intestinal layer, and to intestinal dysmotility degree.

Intestinal manipulation will cause macrophages activation, which will release nitric oxide (NO) and proinflammatory prostaglandins through induced nitric oxide synthase (NOS) and cyclooxygenase-2 (COX-2), resulting in a muscular dysfunction of the intestine. The inactivation of these macrophages with Semapimod, an anti-cytokine molecule, has managed to prevent postoperative ileus in rodents. Low doses of celecoxib (COX-2 inhibitor) have shown to reduce paralytic ileus development after major abdominal surgery in animals, although they have failed to accelerate the recovery of intestinal peristalsis after surgery in humans.

Laparoscopic surgery, which is increasingly spreading in all fields of surgery, especially bariatric surgery, reduces intestinal manipulation and aggression, minimizing the inflammatory bowel response to surgery. Correct surgical technique and careful manipulation of tissues are necessary to prevent the appearance of postoperative ileus.

Inhibitor Nerve Reflexes

There are inhibitory nerve reflexes that act locally through afferent signals from the spinal cord. These reflexes activate the sympathetic system, causing inhibition of intestinal motility. Blocking these reflexes by placing an epidural catheter may also improve postoperative ileus.

Neurohormonal Peptides

Some substances such as nitric oxide, vasoactive intestinal peptide or P substance may also decrease intestinal motility. These substances have also been linked to the appearance of postoperative ileus.

Other substances, such as motilin and ghrelin, are related with improvement of intestinal movements.

Opioids

The inhibitory effect that opioids have on intestinal motility is widely known. They increase muscle resting tone and decrease mobility, causing intestinal spasms in the small intestine and decreasing colonic propulsive movements.

Diagnosis of Ileus

Postoperative ileus diagnosis combines a clinical suspicion and imaging tests. Regardless of the segment of bowel involved, it is imperative to exclude obstructive cause first. The diagnosis of ileus is presumed once obstruction has been excluded.

Gastroparesis

It should be suspected by its symptoms, such as early satiety, nausea, vomiting, eructation, and gastroesophageal reflux. Due to the restrictive component of most bariatric techniques, most of this symptoms can be present in common postoperative course, making it difficult to recognize gastroparesis from an obstruction due to inflammation or stenosis. A gastric emptying x-ray with gastrographin can be used to exclude obstructive causes.

Small-Bowel Ileus

In this entity, abdominal distension is added to the symptoms of gastroparesis previously described. Plain radiographs reveal air-fluid levels and dilated bowel loops. Gastrographin can be used to exclude an obstructive cause, and when in doubt, a CT scan can be used to exclude obstruction (rotation or stricture of the foot of the Roux-n-Y, errors when assembling the circuits, abscess compression, etc.).

Colonic Ileus

Colonic ileus is also characterized by abdominal distension, sometimes marked. Although it is the colon that is primarily involved, up-stream small-bowel dilatation can also be seen if the ileocecal valve is incompetent. CT, contrast enema studies, and endoscopy may help in ruling out mechanical obstruction due to volvulus or a mass lesion.

RISK FACTORS

Risk of developing postoperative ileus may be influenced by different factors. General anesthesia itself has been related to ileus, although this has not been proven. The general risk factors known to date are:

Prolonged Abdominal or Pelvic Surgery

Prolonged abdominal surgery, and pelvic surgery in particular, have been shown as risk factors for developing postoperative ileus in randomized controlled trials.

Open Surgery

Open surgery results in an increased intestinal manipulation, which leads to increased risk of postoperative ileus. Type of incision has not been identified as risk factor for postoperative ileus.

Late Feeding

The outdated use of routinely nasogastric tubes and delayed initiation of oral feeding has been linked to a delay in the onset of intestinal motility. On the other hand, early oral feeding has been associated with earlier onset of intestinal motility.

Intraabdominal Inflammation

Peritonitis itself can cause a situation of intestinal ileus due to bowel inflammation.

Postoperative Complications

Complications such as pneumonia or intestinal abscesses increase the risk of postoperative ileus.

Intra or Postoperative Bleeding

Although estimated blood loss has been associated with postoperative ileus, no differences have been shown for intra- or extra-abdominal bleeding.

Use of Opioids or Other Medications

As mentioned before, opioids are strongly related to postoperative ileus. Other medications may also decrease contractile forces, change patterns of contractions, and/or delay transit throughout the gut: Calcium channel blockers, nitrates, antineoplastic agents, antidiarrheal, oral iron preparations, anticholinergic substances, several antidepressants, antiemetics, etc.

In addition to previously mentioned risk factors for abdominal surgery, there are others conditions, especially prevalent in the obese patient, that can cause intestinal dysfunction, such as:

Diabetes

Diabetes, a co-morbidity with high prevalence in the morbidly obese patient, produces a variety of important metabolic alterations that may impact digestive system. High glucose levels cause neuronal depolarization and increased intracellular calcium (enteric neuron glucotoxicity), causing alterations in the function of the intestinal pacemaker. There may also be a loss of enteric neurons (with decreased Cajal cells and impaired pacemaker function) or neuronal dysfunction. These manifestations are related to neural degeneration typically found in long-term patients.

Many studies have found that patients affected by diabetes mellitus have more gastrointestinal symptoms than control individuals. The most prevalent symptoms are diarrhea, constipation, gastric fullness, heartburn and faecal incontinence, most of which are exacerbated by episodes of stress. With regard to glycemic control, studies are contradictory when establishing a relation between glycemic control and symptom intensity.

Gastroparesis is the main motor complication of diabetes mellitus in the gastrointestinal tract. It is more common in females and no relation to body mass index has been statistically demonstrated. In different studies, gastric emptying dysfunction for solids and liquids has been observed in approximately 50% of diabetic patients. Alterations in gastric motility are mainly: Abnormal relaxation of the gastric fundus altering the gastric accommodation, changes in the motility itself and antral hypomotility after duodenal contraction, secondary to the absence of phase 3 of the migratory motor complex. Pylorus spasm is often observed, which may contribute to deterioration of gastric emptying. Most frequent symptoms are: early gastric plenitude and meteorism rather than nausea or vomiting and are generally correlated with severe alterations in gastric emptying.

Constipation is the main problem related to the large intestine in diabetic patients. It has been documented that colonic transit may be delayed due to autonomic neuropathy. However hyperglycemia itself is capable of inhibiting gastrocolic response, colonic peristaltic waves and rectal perception.

BMI

Some studies have suggested a correlation between body mass index (BMI) and postoperative ileus, although it has not been confirmed in multivariate analysis.

ENHANCED RECOVERY PROTOCOLS: MEASURES TO PREVENT POSTOPERATIVE ILEUS

Many measures have been tested to prevent the appearance of postoperative ileus, although the effectiveness of these measures is unequal. Some of these have not been proven by scientific studies, and even proven harmful to the patient in some cases. The following is a summary of the different measures according to their usefulness and scientific evidence:

EFFECTIVE AND POTENTIALLY EFFECTIVE INTERVENTIONS

Midthoracic Epidural

The epidural use of local anesthetics blocks the afferent nociceptive sensory pathways, achieving correct analgesia and decreasing the need for opioids or other oral analgesics. In addition to this analgesic effect, it also causes a blockage of the efferent sympathetic nerve pathways (T6-L1), which results in a stimulation of intestinal motility and an increase in gastrointestinal blood flow, providing a potential benefit in those patients undergoing major

abdominal surgery. To achieve this effect, the catheter should preferably be placed at the mid-thoracic level (T2-T9), which achieves better analgesic quality, fewer complications and less lower extremity blockages. The use of local analgesics and opioids by epidural route improves pain control without the negative effects that opioids have when administered by other routes.

Epidural catheterization in major laparoscopic abdominal surgery presents better analgesic results than intravenous opioids, however, there are no overall significant differences in postoperative complications. Epidural catheterization does not decrease the average post-surgical hospital stay, but on the other hand it does not increase patient discomfort or anxiety as a result of the technique. There is controversy over whether a return to normal bowel function would be improved, with articles supporting and opposing the latter but with little consistency on both sides of the argument.

Patients undergoing laparoscopic surgery who have had epidural catheterization have a better intraoperative respiratory profile, better oxygenation levels, improved visceral blood flow and lower serum lactate levels, which makes it a good option for patients with restrictive pathology or low vital capacity, as occurs in a large number of obese patients.

Given the above, the risk-benefit of epidural catheterization should be assessed individually, especially in those patients with a worse pulmonary profile predicted, and other types of analgesic strategies, such as blocking the transverse plane, the application of spinal analgesia or opioid analgesia controlled by the patient, should be considered for non eligible patients, in an attempt to avoid the use of opioids with long half-life.

Minimally Invasive Surgery

Laparoscopy is a minimally invasive surgical technique that reduces postoperative pain and, at the same time, preserves intestinal peristalsis, reduces postoperative complications and shortens the length of hospital stay without increasing mortality in patients undergoing major abdominal surgery.

Minimally invasive surgery reduces surgical aggression and bowel manipulation, reducing postoperative ileus. A direct relation between the length of the incision in a laparotomy and the risk of postoperative ileus has been demonstrated.

Mu-Opioid Receptor Antagonists

Methylnaltrexone and Alvimopan are better than placebo for reversing constipation and increased time of opioid-induced gastrointestinal transit, and Alvimopan appears to be safe and effective in treating postoperative ileus. On the other hand, there is insufficient evidence to confirm the safety or efficacy of Naloxone or Nalbufin in the treatment of opioid-induced bowel dysfunction.

Limit the Use of Opioids

As we have already seen, opioids can cause intestinal ileus, so we must avoid them if possible. Nonsteroidal anti-inflammatory drugs, such as ketorolac, are attractive alternatives to opiate analgesics, both for their anti-inflammatory effect and for their opiate-sparing properties. However, they can cause bleeding, renal insufficiency, and gastritis, drawbacks that limit their applicability and duration of use.

Surgical Technique

A meticulous surgical technique, avoiding excessive manipulation, reduces the inflammatory reaction, reducing the risk of postoperative ileus.

Goal-Directed Fluid Therapy

Both deficient and excessive fluid repositioning are associated with postoperative complications. Taking into account that traditionally the insensible losses have been overestimated, which has resulted in an excess in the amount of fluid therapy administered, there is a tendency to use “restrictive regimens,” meaning the replacement of losses during surgery avoiding overload, with the aim of achieving a fluid balance close to zero, without variations in the patient's body weight.

Goal-directed fluid therapy allows the amount of fluids administered to be individually adjusted. It consists of the infusion of fluids boluses, following a protocol, in order to reach a specific hemodynamic or tissue perfusion goal.

Perioperative fluid therapy has a direct effect on surgical results, the prescription of fluids must be adapted to the individual needs of each patient. The objective of fluid therapy in surgical patients is to maintain an adequate circulatory volume, avoiding as far as possible the overload, trying to achieve a zero balance in the perioperative, avoiding weight gain.

The use of goal-guided fluid therapy may reduce postoperative complications and hospital stay in high- and low-risk patients, but associated mortality reduction has not yet been demonstrated.

INEFFECTIVE OR UNPROVEN INTERVENTIONS

Laxatives

Fast-track programs in elective colon surgery have reported that laxatives, together with thoracic epidural analgesia, early oral feeding, and early mobilization, achieve normalization of gastrointestinal function within 48 hours in most patients. A randomized trial showed significantly shorter time to first postoperative bowel movement in the laxative group (a median of 45 versus 69 hours), but there was no effect on postoperative pain or postoperative nausea and vomiting.

Early Enteral Nutrition

Traditionally, food and fluids were avoided postoperatively for a period of time, based upon the assumption that gastrointestinal motility returned slowly; therefore, feeding soon after surgery was expected to result in vomiting and worsened postoperative ileus. Systematic reviews have shown that early enteral nutrition is not harmful and does not result in increased duration of postoperative ileus; rather, it reduces the length of postoperative ileus and hospital stay. However, some patients may not tolerate early postoperative feeding and will experience nausea or vomiting, therefore the benefit remains unproven.

Other Dietary Measures

Chewing Gum

The effect of chewing gum on postoperative bowel recovery has been studied in several randomized trials. Feeding with gum has shown some efficacy in improving bowel function return. Chewing sugarless gum following elective intestinal resection has been associated with a reduction in time to flatus, decreased time to bowel movement, and a reduction in length of hospital stay. Although the analysis is limited by methodologic deficiencies and some heterogeneity, there are no apparent downsides of chewing gum. No differences in postoperative complications, readmissions, or reoperations were demonstrated. Thus, chewing gum to accelerate postoperative gastrointestinal recovery can be suggested.

Bran

Two small observational studies investigating the use of 8 to 10 days of preoperative bran supplementation reported that patients on supplemented diets were more likely to pass flatus within 24 hours of surgery (78 versus 5 percent). Still more evidence is required to reach a recommendation level.

Coffee

The effects of coffee intake on bowel motility appear to be related to alterations in colonic motor activity, but whether this is related to caffeine or other components in the coffee is unknown. Coffee consumption significantly decreased the time to the first bowel movement, time to tolerance of solid food, and time to first flatus. Although promising, use of coffee for this purpose is yet to be established.

Pharmacologic Treatment

With the exception of peripherally acting mu-opioid receptor antagonists (e.g., alvimopan) discussed above, no other pharmacologic treatments (including metoclopramide, erythromycin, or neostigmine) have shown benefits in accelerating postoperative gastrointestinal recovery. A variety of other agents targeting the known pathophysiologic pathways are under investigation.

Early Mobilization

Bed rest increases insulin resistance, loss of muscle mass and strength, and alters lung function. Early mobilization after surgery has been proposed as a possible way to counteract insulin resistance due to immobilization and reduce respiratory complications.

No studies have been found in the scientific literature aimed specifically at evaluating the influence of early mobilization, on the day of surgery, as a preventive measure of postoperative ileus.

The only study evaluating the effect of early postoperative mobilizations on the resolution of postoperative dysmotility did not find a benefit. However, early ambulation is recommended for its other benefits, most notably reduction in thromboembolic complications.

Gastrografin

Gastrografin is a water soluble, hyperosmolar oral contrast agent commonly used for computed tomography (CT) imaging. Although Gastrografin has been used therapeutically to treat adhesive small bowel obstruction [93], its efficacy in treating prolonged postoperative ileus remains unproven. Based upon available evidence, we do not recommend using Gastrografin in the treatment of prolonged postoperative ileus beyond diagnostic purposes.

Gastrografin has been studied in two small randomized trials of patients who had prolonged ileus after surgery. In one trial, orally administered Gastrografin accelerated time to flatus or stool (18.9 versus 32.7 hours) and time to resolution of abdominal distension (52.8 versus 77.7 hours), but did not affect time to resolution of nausea and vomiting (64.5 versus 74.3 hours) or time of tolerance of oral diet (75.8 versus 90.0 hours) [94]. The other trial reported no significant differences in mean time to resolution of postoperative ileus between the Gastrografin and control groups (9.1 versus 10.3 days), but length of stay, time needing a nasogastric tube, and time until tolerance of oral intake all tended to improve with Gastrografin.

POTENTIALLY HARMFUL INTERVENTIONS

Routine Use of SNG

The use of a nasogastric tube as gastrointestinal decompression method is not recommended for it has proven to: delay oral tolerance, delay hospital discharge, not to improve intestinal function and to not prevent anastomotic failure, fascia dehiscence or incisional hernia. It is also useless in avoiding pulmonary complications (atelectasis, aspiration, pneumonia, fever and pharyngolaryngitis) nor abdominal discomfort (abdominal distension, nausea and vomiting). Patients recover intestinal mobility earlier without NGS, achieving oral tolerance in 80-90% of patients in the first 24 hours and associated shorter hospital stays, lower risk of infections and improvement of hyperglycemic control.

COX-2 Inhibitors

Intestinal manipulation appears to increase cyclooxygenase-2 (COX-2) expression and rise prostaglandin levels, which, in turn, decreases jejunal contractility. COX-2 inhibition may improve gastrointestinal motility. One randomized trial reported that patients treated with a COX-2-specific inhibitor had a significantly shorter recovery time (time to return of bowel sounds, first bowel movement, tolerance of solid diet, and discharge) and less opioid use when compared with patients on a standard postoperative patient-controlled analgesia (PCA) morphine-only regimen after colorectal resection. However, these agents are associated with a variety of adverse effects, particularly disturbances in intestinal healing leading to potential risk of anastomotic dehiscence.

Chapter 267

PROPHYLAXIS OF STRESS ULCERS, ANASTOMOTIC ULCERS AND GASTROESOPHAGEAL REFLUX DISEASE

Pablo Priego*

Department of General Surgery, Division of Esophagogastric and Bariatric Surgery,
Ramón y Cajal University Hospital, Madrid, Spain

ABSTRACT

Although stress ulcers are not a specific complication after bariatric surgery, its incidence and mortality among all patients in intensive care unit is not insignificant. Anastomotic or marginal ulcers (mainly after Roux-en-Y gastric bypass) and gastroesophageal reflux disease (GERD) are two situations more related to bariatric surgery. Association between GERD and obesity is extremely important, not only because several studies have shown that weight loss and lifestyle modifications are important in reducing the symptoms of GERD, but also because different surgeries have different impacts on the GERD symptomatology and that careful assessment may be needed before performing bariatric surgery in patients with GERD. Recommendations about prophylaxis, treatment and how to avoid these problems are described in this chapter.

Keywords: stress ulcers, anastomotic ulcers, marginal ulcers, gastroesophageal reflux disease, bariatric surgery, prophylaxis, treatment

INTRODUCTION

Stress-related gastric mucosal damage or stress ulceration (SU) has been documented to occur after many major physiologic insults, including trauma, major operative procedures, burn injury and during critical illness [1]. SU were once a major cause of morbidity and

* Corresponding Author's Email: papriego@hotmail.com.

mortality in critically ill patients. However, with the advent of ulcer prophylaxis and improved critical care, surgical intervention is only necessary for a small number of patients with life-threatening hemorrhage or perforation [2]. Different aspects of epidemiology, pathophysiology, risk factors, prognosis and prophylaxis of SU in the intensive care unit (ICU) are discussed in this chapter [3].

Obesity is an epidemic on the rise all over the world. The Roux-en-Y gastric bypass (RYGB) is the most used bariatric surgical procedure worldwide. Marginal ulceration (MU) remains a morbid complication of RYGB, occurring in 1% to 16% of patients [4]. Although the mechanisms underlying the development of MU have not been completely elucidated, ulcers may be caused by the peptic action of the acid juice from the gastric pouch acting on the small bowel not alcalinized by biliopancreatic juice. Prevention and management of MU after RYGB is still a matter of debate. Different aspects regarding risk factors, prophylaxis, recommendations and treatments are analyzed [5, 6].

To end up, there is an interesting relationship between gastroesophageal reflux disease (GERD) and bariatric surgery [7, 8]. The prevalence of GERD has been described in >50% of obese patients. Increases in the prevalence of obesity and GERD have paralleled one another over the past decade. Several studies have shown that weight loss and lifestyle modifications are important in reducing the symptoms of GERD [9]. Association between obesity and GERD is extremely important, because a critical review of the literature suggests that different surgeries have different impacts on the symptomatology of GERD and that careful assessment may be needed before performing bariatric surgery in patients with GERD. Different aspects of GERD pathophysiology regarding different bariatric procedures, outcomes and recommendations will be discussed.

STRESS ULCERS PROPHYLAXIS

Stress ulcers usually occur in the fundus and body of the stomach, but sometimes develop in the antrum, duodenum, or distal esophagus. Normally, SU tend to be limited to superficial capillary; however, deeper lesions may also occur and cause massive bleeding or perforation. Incidence of gastrointestinal (GI) bleeding range from 1.5 to 8.5 percent among all ICU patients, but may be as high as 15 percent among patients who do not receive stress ulcer prophylaxis [10]. Furthermore, GI bleeding due to SU is associated with increased mortality. In the prospective cohort study of Cook et al. [10], mortality was higher among ICU patients with clinically important GI bleeding than among those without bleeding (49% vs. 9%).

Pathogenesis

The exact mechanism by which gastric SU develops remains controversial. Classically, it has been as a result from an imbalance between mucosal protection and gastric acid production.

- a) *Impaired mucosal protection:* The stomach is normally protected by a glycoprotein mucous layer that forms a physical barrier to hydrogenion diffusion and traps

bicarbonate. This barrier may be denuded by increased concentrations of refluxed bile salts or uremic toxins, which are common in critically ill patients [11, 12]. In addition, its synthesis may be decreased when there is poor gut perfusion caused by shock, sepsis, or trauma [13, 14].

- b) *Hypersecretion of acid*: Hypersecretion of acid due to excessive gastrin stimulation of parietal cells has been detected in patients with head trauma. However, excessive gastric acid production is probably not the principle factor leading to its development, as a pH greater than 3.5–4.0 is evident in only 20–60% of critically ill patients [15–17].

Finally, *Helicobacter pylori* infection may also contribute to SU, but the evidence is of limited quality [18, 19].

Risk Factors

Based on the current literature review, the most universally accepted risk factors for SU are prolonged mechanical ventilation (more than 48 h) and coagulopathy [20]. The incidence of clinically important GI bleeding among patients with one or both of these risk factors was 3.7 percent, compared to 0.1 percent among patients with neither risk factor.

Other identified risk factors for SU include shock, sepsis, multiple injuries, spinal cord injury, hepatic failure, acute renal failure, and requirement of high-dose steroids [20, 21].

Glucocorticoid therapy alone has not been conclusively shown to be a risk factor for stress ulceration [20], however, it is commonly cited as an indication for stress ulcer prophylaxis [22].

Prophylaxis

Based on guideline recommendations, SU prophylaxis should be administered to all critically ill patients who are at high risk for GI bleeding [23–25]. That includes:

- Coagulopathy, defined as a platelet count $<50,000$ per m^3 , an International Normalized Ratio (INR) >1.5 , or a partial thromboplastin time (PTT) >2 times the control value
- Mechanical ventilation for >48 hours
- History of GI ulceration or bleeding within the past year
- Traumatic brain injury, traumatic spinal cord injury, or burn injury
- Two or more of the following minor criteria: sepsis, an intensive care unit (ICU) stay more than one week, occult GI bleeding for six or more days, or glucocorticoid therapy (more than 250 mg hydrocortisone or the equivalent)

In addition, many physicians also provide SU prophylaxis to patients with traumatic brain injury, traumatic spinal cord injury, or thermal injury (>35 percent of the body surface area) [26].

Another important question is whether a patient who is receiving enteral nutrition also requires pharmacological SU prophylaxis. Based on different observational and randomized trials, it is known that enteral nutrition alone may reduce the risk of GI bleeding due to SU and that SU prophylaxis may be ineffective or harmful among these patients [27-30].

Recommendations

Regarding last update revision of Weinhouse et al. [3] about stress ulcers prophylaxis in the intensive care unit, final recommendations are the following:

- In critically ill patients, histamine-2 receptor antagonists (H2 blockers), proton pump inhibitors (PPIs), and antacids reduce GI bleeding when compared to placebo or no prophylaxis.
- For critically ill patients who have risk factors for SU, it is recommended prophylaxis with agents that suppress gastric acid (eg, PPI, H2 blockers, antacid) rather than no prophylaxis (*Grade 1B*).
- For critically ill patients without risk factors, SU prophylaxis should be considered on a case-by-case basis. Considerations include whether the patient is receiving enteral nutrition, how long the patient is expected to be without enteral nutrition, the severity of the patient's illness, and the patient's comorbidities.
- For critically ill patients who are able to receive enteral medications and in whom SU prophylaxis is indicated, it is suggested an oral PPI rather than an alternative prophylactic agent (*Grade 2B*).
- For critically ill patients who cannot receive enteral medications and in whom SU prophylaxis is indicated, it is suggested an intravenous H2 blocker or an intravenous proton pump inhibitor (*Grade 2B*).

BARIATRIC SURGERY AND MARGINAL ULCERATION

Marginal ulceration remains a morbid complication of RYGB, occurring in 1% to 16% of patients [4]. According to the literature, 60% of marginal ulceration develops within 6 months after RYGB. However, they can occur up to 5 years postoperatively [5].

Clinical appearance of MU ranges from asymptomatic, severe abdominal pain, lack of appetite, abnormal weight loss, or nausea and vomiting. Furthermore, MU may cause anemia due to chronic occult bleeding (10.2% of patients after RYGB), stomal stenosis or perforation [5]. The diagnosis of a marginal ulcer is established by upper endoscopy.

Although the mechanisms underlying the development of marginal ulceration have not been completely elucidated, the etiology of this complication is likely to be multifactorial [6]. Traditionally, numerous mechanisms underlying the development of MU have been currently discussed in the literature. These can be divided into surgical and nonsurgical risk factors [5]. Concerning *surgical risk factors*, small-vessel ischemia and anastomotic tension are suggested as the most important causes [31]; but persistent acidity in a large gastric pouch [32] and foreign body reaction has also been involved [33, 34]. On the other hand, concerning

nonsurgical risk factors can be included, exogenous substances (smoking, NSAID), and *H. pylori* infection [35-37].

In order to identify independent risk factors for MU and with a follow-up of 64 months and 3% of marginal ulcer rate, Bhayani et al. [38] have reported that on univariate analysis, hypertension, gastroesophageal reflux disease, hyperlipidemia, and sleep apnea were significantly correlated with margin ulceration. However, on multivariate analysis, the odds of marginal ulcer formation were 7.84 among hypertensive patients with a 95% confidence interval of 1.75-35.06 ($P = 0.007$). In this study, preoperative hypertension was the only significant predictor of marginal ulcer disease.

Gastric Acid

Classically, the role of gastric acid has been considered essential for development of marginal ulceration [6]. However, recently studies have found a virtual absence of acid secretion within the gastric pouch after gastric bypass in patients with marginal ulcers [32, 39].

Theoretically, the secretion of gastric acid from parietal cells of gastric pouch will lead to a peptic digestion of the unprotected jejunal mucosa, causing the marginal ulceration [32]. Furthermore, the gastrojejunostomy is not reached by the alkaline fluid secreted by glands of the duodenum. Therefore, the gastrojejunal anastomosis may be exposed to the undiluted acidic juice produced by the gastric pouch, subsequently leading to margin ulceration development. For this reason, large pouch size (>50 ml) was thought to predispose patients to marginal ulceration. Indeed, reducing the size of the gastric pouch has shown to decrease the incidence of marginal ulcers [40].

Another question regarding the gastric pouch is the orientation. It is known that the lesser curvature has a high concentration of parietal cells, so if we create a pouch limited to the cardia as Sapala et al. [41] proposed; the rate of marginal ulceration would decrease.

Stapled line leakage with a resultant gastrogastic fistula is another factor that could increase the rate of marginal ulceration. If the gastric remnant is connected with the pouch, the greater volume of low-ph fluid will digest the jejunal mucosa, and the incidence of marginal ulceration will be higher [6].

Anyway, and to summarize gastric acid seems to predispose patients to the development of marginal ulcers, supported by evidence that acid suppression alone is effective in healing marginal ulcers.

Foreign Body

The foreign body (staples or suture material) used to build the anastomoses between the gastric pouch and the jejunum has been suggested to cause an inflammatory reaction and lead to ulcer formation. Furthermore, several studies have reported that the marginal ulceration rate was significantly higher when the gastrojejunal anastomoses were created with stapler or permanent suture rather than absorbable suture [34, 42]. In contrast, the technique used to fashion the gastrojejunostomy (hand sewn vs. linear vs. circular) was not found to have an impact on marginal ulceration development in other studies [43].

Exogenous Substances

In the same way as in the general population, non-steroidal anti-inflammatory drugs (NSAID) are believed to predispose to marginal ulceration after RYGB [44]. Furthermore, smoking is also related with the development of marginal ulceration [45]. Regarding smoking, some bariatric surgeons consider leaving smoking a condition prior to perform any bariatric procedure.

Helicobacter Pylori

Classically, *helicobacter pylori* has been implicated as a possible etiology agent in the development of margin ulcers after RYGB [46]. Theoretically, patients preoperatively screened and treated for *H. pylori* had fewer incidences of margin ulcers than those not screened or eradicated [47]. On the other hand, Rasmussen et al. [6] have demonstrated that preoperative *H. pylori* infection, although adequately treated was higher among patients who had a marginal ulceration (32%) as among those who did not (12 %) [48].

Prevention and Management

Prevention and management of marginal ulceration after RYGB is still controversial. Proton pump inhibitors (PPIs) are an efficient option for the prevention and treatment of peptic ulcers [49]. However, despite the preventative use of treatment-dose PPIs, marginal ulceration may still occur in up to 16% of post-RYGB patients [5].

Nevertheless, the management of marginal ulceration after RYGB can be treated conservatively or surgically. Conservative treatment includes the eliminating known risk factors of peptic ulcers (Smoking, alcohol, NSAIDs, stress, hypertension), and treatment with antacids (PPI). Initial medical treatment consists of gastric acid suppression with a six-week course of PPI, with or without the addition of sucralfate, followed by a repeat endoscopy to ensure healing. An upper gastrointestinal series or a computed tomography (CT) scan with oral contrast should be performed to rule out a gastrogastic fistula, because this complication is associated to 72% of marginal ulceration [31].

The success rate of this conservative management ranges between 68 to 88% [31, 50, 51]. Hereby, most of bariatric surgeons employ PPI as the first-line and single treatment. However, it is important to notice that there is no consensus regarding the duration of therapy and whether therapy should be continued after marginal ulceration resolution. Furthermore, the correct dosage and the need for combination of different acid reducing agents remain unclear [5].

Despite the best conservative therapy, 30% of patients will need surgical revision for therapy refractory or recurring marginal ulceration [5, 39]. Surgical options are various and include redoing the gastrojejunostomy combined with pouch resizing. In a classical study this technique was successful in up to 87% of cases [5]. Other surgical options are reduction of acid production by truncal vagotomy [52] or gastric remnant resection, pouch resection with subsequent esophagojejunostomy, and RYGB reversal. However, although feasible, RYGB reversal has not been shown to be an effective marginal ulceration treatment [53, 54].

In unstable patients, due to a perforated peptic ulcer, a Graham patch can be used to seal any perforation, the local area washed out, and a feeding tube placed.

Unfortunately, there is no consensus for the prevention and management of primary or refractory anastomotic ulcer, and no recommendations can be drawn from the available literature. So it is advised to create more multicenter and prospective studies in order to define strategies of prevention and treatment of this painful and unresolved condition after RYGB.

BARIATRIC SURGERY AND GASTROESOPHAGEAL REFLUX DISEASE (GERD)

The prevalence of gastroesophageal reflux disease (GERD) has been described in >50% of obese patients compared to 10-20% in the general population. Increases in the prevalence of obesity and GERD have paralleled one another over the past decade [8, 55]. Moreover, and because the prevalence of GERD is markedly higher in overweight and obese individuals as compared to those with normal BMI, GERD itself is now recognized as a obesity-related comorbidity [56, 57].

The etiology is not completely understood, but basically, the development of GERD is due to a failure of the anti-reflux barrier that comprises the lower esophageal sphincter (LES) and the crural portion of the hiatus. Normally, this is associated to an increased pressure from the stomach secondary to a hiatus hernia or increased intra-abdominal pressure [8].

This failure of the anti-reflux barrier can lead to either short-term symptoms including heartburn, regurgitation, dysphagia and chest pain or long-term ones like esophagitis, strictures, Barrett esophagus or esophageal adenocarcinoma [7].

Association between obesity and GERD is extremely important, because a critical review of the literature suggests that different surgeries have different impacts on the symptomatology of GERD and that careful assessment may be needed before performing bariatric surgery in patients with GERD. Indeed, when surgical treatment of GERD is indicated in a severely obese patient, bariatric surgery rather than fundoplication should be strongly considered. However, diagnosis of GERD in obese patients is not always easy to do. Many patients with subjective claims of GERD have serious difficulties to correlate objectively with esophageal functional studies, making studies based on subjective claims difficult to analyze.

Several studies have shown that weight loss and lifestyle modifications are important in reducing the symptoms of GERD. However, with regards to bariatric surgery and its effect on GERD, studies have shown inconsistencies with different types of bariatric surgery. Pallati et al. [58] presented a prospective study with the Bariatric Outcomes Longitudinal Database (American Society of Metabolic and Bariatric Surgery Center of Excellence program) in order to compare the efficacy of various bariatric procedures in the improvement of GERD. Of a total of 116.136 patients, 36.938 patients had evidence of GERD preoperatively. After excluding patients undergoing concomitant hiatal hernia repair or fundoplication, there were 22.870 patients with 6-month follow-up. All common bariatric procedures improve GERD; however, GERD score improvement was best in RYGB patients (56.5%; 7955 of 14.078) followed by Adjustable Gastric Banding (46%; 3773 of 8207) and Sleeve Gastrectomy patients (41%; 240 of 585).

Gastric Banding

The effects of Laparoscopic Adjustable Gastric Banding (LAGB) on GERD are controversial [7]. While for several studies, LAGB appears to provide short-term improvement of reflux symptoms, esophagitis and normalized pH monitoring results [59]. There is, however, a group of patients who experience a new reflux symptoms and esophagitis in the long term, although it is difficult to be sure whether these are a result of pathologic GERD or complications from gastric banding [60-62]. The mechanism by which LAGB may improve GERD is not well characterized, but is thought to include weight loss, increase in LES pressure, and reconstitution of the angle of His. On the other hand, it has been supposed that the poorer GERD outcomes following LAGB might be attributable to an unrecognized hiatal hernia at the time of initial band placement, which has led most bariatric surgeons to suggest that the presence of hiatal hernia is a contraindication to LAGB [63].

Sleeve Gastrectomy

Sleeve gastrectomy (SG) has reached wide popularity during the last decades, due to the lower morbid-mortality rates in compare to RYGB, and the excellent results regarding weight loss and resolution of comorbidities. Moreover, SG has rapidly become popular as a standard alone bariatric operation. At the same time, there are some concerns regarding its long-term results and postoperative GERD. As with LAGB, early data regarding the impact of SG on GERD are controversial too, and very little long-term or comparative data regarding SG and GERD are available [7].

Classically, sleeve gastrectomy has been associated with an increase rate of postoperative reflux. However, the interpretation of the results are not standardized, because most studies investigate the presence of GERD by assessing symptoms and the use of PPI reducing medications only [9]. In 2011, Chiu et al. [64] performed a systematic review on 15 studies in order to evaluate the effect of SG on GERD. Four of these studies found an increased prevalence of GERD after SG, and seven showed reduced prevalence of GERD after SG, so results were inconclusive.

To date, only a few studies objectively analyzed patients by esophageal manometry and 24 ph-metry [65-73]. Regarding manometric changes, published data were controversial [65-71]. Some small studies [65] have found a significant decrease in LES, proposing the partial section of the sling fibers of the cardia as cause of this finding. On the other hand, Petersen et al. [66] reported an increase in LES pressure regardless of the weight loss, proposing that this manometric change was related to the position of the stapler regarding to the angle of His. The closer the staple line to the gastroesophageal junction, the higher the LES pressure is.

Indeed, only 4 studies [68, 70-72] have objectively study the presence of pathologic reflux by 24-h Multichannel Intraluminal Impedance ph-metry (MII ph-metry) monitoring or 24 ph-metry with same controversial results. Meanwhile, Del Genio et al. [68], Gorodner et al. [70] and Georgia et al. [71] showed a significant increase of the median DeMeester's score (almost 2.5 times higher than the preoperative one) and "de novo" GERD after SG (already 30%), Rebecchi et al. [72] showed a significantly decreased DMS and total %ph, with only a 5.4% of "de novo GERD."

Meanwhile, data regarding LES function are controversial, it is suggested that there is an important role of the surgical technique on the incidence of postoperative GERD [9]. Main surgical technical issues are: a relative narrowing of the mid portion of the sleeve, a redundant upper part of the sleeve and the presence of a concomitant hiatal hernia [73].

- a) The shape of the gastric sleeve plays a major role in leading to GERD. The remnant gastric pouch, being much more restrictive, may increase gastric pressure by reducing gastric compliance and emptying, and decreasing volume and dispensability [7]. Keidar et al. [75] found that most part of patients when a barium swallow was performed had a combination of dilated upper portion of the sleeve and relative narrowing of the mid-stomach. These two anatomical situations were due to a too narrow construction of the sleeve in association with retention of part of the gastric fundus by stapling far away from the left pillar of the crura, in order to decrease the rate of leakage.

Avoiding any anatomical obstruction at incisura angularis level, we can reduce the pressure in the proximal gastric sleeve and reduce leak rates in the short term and fundus dilatation and/or GERD in the long term. Another important factor appears to be distance of the final staple line from angle of His. It is true that going too close to esophagus, the leaks rate increases and going too far risks leaving behind a bigger fundus and may predispose to reflux. Stapling 1 cm away from the angle of His would appear to be a reasonable compromise in most patients.

On the other hand, SG may also contribute to reducing of GERD by accelerating gastric emptying and increasing weight loss, it is associated with a decrease of abdominal pressure. It was also suggested that long-term resolution of GERD could be explained by increase in compliance and restoration at the angle of His, which occurs about 3 years postoperatively [7].

- b) The impact of the size of the bougie on the prevention of GERD after SG is unclear [76]. While it is known that smaller bougies are associated with leaks secondary to gastric strictures at incisura angularis, the use of larger bougies might also favour the development of GERD due to a reduce of weight loss, dilation of upper part of stomach and in consequence an increased number of residual parietal cells [9].
- c) Finally, the presence of a hiatal hernia is not considered by many surgeons a contraindication to SG [76]. However, results remain controversial because all studies based their results on symptom evaluation instead of assessing postoperative GERD with 24-phmetry. Recently, a study of Mahawar et al. [77] has tried to investigate the results and technical aspects of simultaneous SG and hiatal hernia repair, but although most studies reported a decrease on GERD symptoms when hiatal hernia was repaired, these results were opposite to other ones found by other authors [78, 79].

Different authors have proposed several associated techniques in order to treat GERD simultaneously to the performing of SG. Recently, Nocca et al. [80] presented their preliminary pilot study of patients operated with a Nissen anti-reflux valve added to a standard SG (N-Sleeve). Authors report that this technique provides an adequate reflux

control with no clear interference on the expected bariatric results of a standard SG with a 1 year follow-up.

Other technical option has been described by Da Silva et al. [81]. They have proposed an alternative technique of sleeve gastropasty combined with Nissen fundoplication for morbidly obese patients who present significant GERD called Laparoscopic Sleeve-Collis-Nissen gastropasty (LSCNG). With a population of 122 patients, one-year follow-up showed a significant decrease in the prevalence of esophagitis (100 vs. 13.6%) and the use of PPIs (92 vs. 13.6%). The percentages of excess weight loss 1 and 3 years after the surgery were 64.4 ± 7.2 and $60.4 \pm 8.1\%$, respectively. However, although LSCNG is a novel, technically feasible surgery with a low incidence of procedure-related complications, prospective studies are required to assess the real impact of this procedure on the improvement of GERD symptoms.

Finally, Galvez-Valdovinos et al. [82] has recently published an old technique for treatment of GERD, but specially adapted to treatment of GERD in patients in which a SG is going to be performed. In this study, 15 patients with SG who presented with hiatal hernia and GERD, a ligamentum teres cardiopexy was performed. In this procedure, the ligamentum teres is released from its umbilical connection and the hernia reduced by manual traction, freeing the last 3–5 cm of esophagus in the abdomen. The distal ligamentum teres is fixed with one stitch to the apex of the angle of His, one at the gastroesophageal junction, and one joining the gastric fundus to the esophagus. The remainder of the ligamentum teres is fixed over itself with four to six stitches, forming a necktie cardiopexy. The procedure concludes with diaphragmatic crura closure. After 6 months, 13 patients (86.6%) achieved successful results, defined as resolution of GERD, no PPI use, and manometry measurement over 12 mmHg after surgery. However, two patients (13.3%) required continued PPI.

On the other hand, and once GERD has occurred after SG, medical therapy with PPIs represents the initial treatment of choice [83, 84]. However, in case of failure of PPI therapy, conversion to RYGB is suggested [85, 86]. Very recently, new approaches like the LYNX® Reflux Management System and the Stretta® procedure have been proposed in patients with GERD and hypotensive LES [87, 88].

To summarize, prospective and randomized studies with long follow-up and objective evaluation of GERD are needed before drawing a conclusion. As such, SG in the setting of significant GERD should be recommended with caution. However, whether a SG has to be carried out in presence of hiatus hernia (severe adhesions, Crohn's disease, patient preference, etc.), attention should be paid to several technical factors in order to reduce incidence and prevalence of GERD postoperatively.

Roux-En-Y Gastric Bypass

RYGB accounts for over half of the currently performed bariatric operation in the United States, and seems to be the most effective bariatric procedure in the alleviation of GERD [89, 90]. Nowadays, it is considered as the gold standard bariatric procedure for obese patients with symptoms of GERD and/or presenting hiatal hernia.

It is also important to note that some studies have assessed the use of RYGB as revision surgeries to laparoscopic Nissen fundoplication procedures that have failed to alleviate GERD symptoms or as I have mentioned before in patients with previous SG in which uncontrolled

GERD has developed. Moreover, several studies have reported it is also very effective in treating symptoms related to GERD in a similar way that with Nissen fundoplication [91-93].

Its efficacy in treating GERD is thought to be related to the relatively low acid production of the small-volume (15-30 ml) gastric pouch. As I have mentioned before in the pathophysiology of marginal ulceration, the cardiac region of the stomach where the pouch is created has been shown to lack parietal cells, so it should not produce acid. Smith et al. [94] have shown basal and stimulated gastric acid secretion to be virtually absent from the gastric pouch after RYGB. Moreover, bile reflux is also eliminated using an alimentary limb measuring at least 100 cm in length. Furthermore, the small pouch minimizes any reservoir capacity to promote regurgitation [89]. Finally, RYGB improves GERD because of the additional benefit of significant weight loss.

Basically, maybe one of the most important factors that contributes to GERD improvement is the size of gastric pouch. Indeed, if we compare GERD remission in super-obese patients ($\text{BMI} \geq 50 \text{ kg/m}^2$) who underwent RYGB with duodenal switch (DS), the first ones had a higher rate of GERD resolution than those who underwent DS, despite the greater weight loss seen in the latter group [94].

Some studies that included patients with morbid obesity and RYGB have reported complete improvement of symptoms in 80% of the cases and discontinuation of anti-secretory therapy in 97% of them [90, 94, 96].

Mejía-Rivas et al. [96], observed that the mean weight loss 6 months after RYGB was $42.5 \pm 9.7 \text{ kg}$, representing 71% of the decrease in the weight excess. Moreover, 6 months after surgery, reflux symptoms disappeared in 90% of the patients. Indeed, the abnormal exposure to acid in the esophagus was normalized in 95% of the cases and the percentage of time with $\text{pH} < 4$ decreased from 10.7 ± 6 to 1.6 ± 1.2 after RYGB. There also was a significant reduction in the number of reflux episodes, number of long refluxes, DMS and symptom index. Symptoms after RYGB were heartburn in 10% and regurgitation in 5% of the patients. None of the patients had dysphagia.

These results were very similar to those obtained by Patterson [97] and Ortega [98] in that they observed that weight reduction after a RYGB favors improvement in reflux symptoms and decrease in the esophageal exposure to acid measured by an ambulatory 24-h pH-metry.

To sum up, nowadays RYGB is considered treatment of choice of patients with obesity and GERD symptoms; however, as I have mentioned before and following the results published in literature regarding SG, could be performed in selected cases.

Chapter 268

POSTOPERATIVE PAIN PROPHYLAXIS AND MANAGEMENT

Carmen Vallejo Lantero*, MD and Esther García Villabona, MD

Anesthesiology Department of Hospital Universitario de La Princesa, Madrid, Spain

ABSTRACT

Increasing numbers of patients with morbid obesity are presenting for surgery and their acute pain management requires an evidence-based clinical update. Due to the strong association between obesity and certain medical conditions, bariatric surgery patients are at increased risk for a variety of medical complications after surgery. Obstructive sleep apnea is extremely common in obese bariatric surgical candidates. Though overall evidence is limited, multimodal analgesia with a step-wise, severity-based, opioid-sparing approach appears to improve acute pain management in morbid obesity. The perioperative use of non-opioid adjuvants appears to offer further improvements in patient's safety and outcomes.

Keywords: pain management, bariatric surgery, obesity, postoperative pain, opioid-sparing

INTRODUCTION

Morbid obese population is increasing every year worldwide, and laparoscopic bariatric surgery has a central role in their treatment. The pathophysiology of obesity, typical comorbidities and the high prevalence of obstructive sleep apnea (OSA) amongst patients make safe analgesic management difficult. Studies have indicated that the incidence of OSA may be as high as 77% in those seeking surgery [1]. Narcotic pain medications can decrease upper airway tone and unmask or exacerbate sleep apnea [2]. Apneic episodes precipitating heart block perioperatively in bariatric surgery patients have also been documented [3]. For these reasons, the American Society of Anesthesiologists task force on perioperative

management of patients with OSA recommends minimizing or avoiding perioperative narcotic administration to these patients [4].

Therefore, acute pain management in overweight patients poses two main problems: choice of the most suitable and safest analgesic techniques specific to this patients group and an appropriate location to provide these techniques, the monitoring, required to assure their safety [5].

The goal of postoperative pain management is the provision of comfort, early mobilization and improving respiratory function without causing inadequate sedation and respiratory compromise. Though overall evidence is limited, multimodal analgesia with a step-wise, severity- based, opioid-sparing approach appears to improve acute pain management in morbid obesity. The perioperative use of non-opioid adjuvants appears to offer further improvements in patient's safety and outcomes [6].

RISK FACTORS FOR POSTOPERATIVE PAIN IN MORBID OBESITY

Obstructive Sleep Apnea in Obesity

In morbid obesity, conventional opioid-based acute pain during intraoperative and postoperative pain management is associated with the risk of sedation, airway obstruction and respiratory depression. This is particularly common in patients with various types of sleep disordered breathing, including OSA. Opioid administration is associated with central apnea, and has been reported to enhance obstructive apnea in predisposed patients. Because of the high incidence of OSA in obese patients and other studies showing that morbidly obese patients have increased perioperative obstruction and desaturation even without OSA, the focus with regard pain management has to be on opioid sparing multimodal approaches [7]. Efforts to limit complications from postoperative pain management have led to expert opinion based guidelines for postoperative care of patients with OSA. Prominent amongst these are the recommendations to avoid background or continuous infusions with Patient Controlled Analgesia (PCA) systems, appropriate level and duration of postoperative monitoring. The guidelines prefer exclusion of opioids from neuroaxial techniques in favor of local anesthetics and the use of non-steroidal anti-inflammatory drugs (NSAIDs) to reduce adverse events of opioids by opioid-sparing effects. They recommend supplemental oxygen postoperatively and continuous positive airway pressure (CPAP) or non-invasive positive pressure ventilation (NIPPV) in the postoperative setting for patients using these modalities preoperatively [4]. Regarding monitoring, the guidelines favor continuous pulse oximetry with observation (in ICU or step-down unit, by telemetry or observer), but not intermittent bedside monitoring. Intense monitoring should be continued until saturation remains above 90% during sleep without supplemental oxygen.

Drug Dosing

The physiological changes associated with morbid obesity impact upon the pharmacokinetics of anesthetic and analgesic drugs. Drug dosing is generally based on the

volume of distribution for the loading dose and on the clearance for maintenance. In the obese patient, the volume of distribution is increased if the drug is distributed both in lean and fat tissues whereas the anesthetic drug clearance is usually normal or increase. When calculating dosing based on weight, it is important to consider that using the patient's total body weight can result in overdosing medications [6]. Obesity increases both fat and lean masses; however, the percentage of fat tissue increases more than does the lean mass, affecting the apparent volume of distribution of anesthetic drugs according to their lipid solubility [8]. With the exception of neuromuscular antagonists, lean body weight (LBW) is the optimal dosing scalar for most drugs used in anaesthesia including opioids and anaesthetic induction agents, especially as cardiac output is significantly correlated to LBW, except in individuals with obesity cardiomyopathy [9]. As we see the different possibilities in the treatment and prevention of pain in the obese patient, we will indicate the most appropriate doses for each one of them.

PAIN MANAGEMENT IN OBESE PATIENT

The role of multimodal analgesia and non-opioid adjuvant therapy has been shown to be beneficial in a variety of procedure-specific postoperative pain management protocols. In the general surgical population, Enhanced Recovery after Surgery (ERAS) protocols have shown that effective postoperative pain management is an essential component of recovery outcomes, as it promotes early feeding, ambulation and discharge with reduced complications. In patients with morbid obesity, these specific outcomes would also not be desirable, they are probably essential [6]. Recent data on the efficacy and safety of multimodal pain management strategies for weight loss surgery are consistent with this accepted approach of opioid-sparing postoperative analgesia in the general surgical patient population [10]. It is widely accepted adjuvants such as ketamine, lidocaine and pregabalin, directed to the management of acute hyperalgesia, play a mayor role in the treatment of acute pain in morbidly obesity.

Acetaminophen and NSAIDs

Non opioid analgesics should be considered wherever possible.

- *Acetaminophen* has been repeatedly shown to decrease opioid requirements in the perioperative setting and even contribute to shorter length of stay. Obese patients have increased rates of hepatic phase 2 conjugation and clear acetaminophen rapidly, but whether dosing intervals should be reduced and daily doses increased is highly contentious. A small subset of morbidly obese patients go on to develop hepatic steatosis and ultimately cirrhosis, so increased dosing as a routine is not without risks, and caution is advised. *Acetaminophen is an important foundational (World Health Organization WHO Step I) analgesic for optimal pain control with decreased opioid consumption (Grade B)* [6].

- *Ketorolac*. Non-steroidal anti-inflammatory drugs are the most widely used component of multimodal anesthesia. The perioperative use of ketorolac alone or in combination with local anesthesia leads to significant improvement of postoperative pain control⁵. Similarly, an intraoperative infusion of ketorolac reduced pain scores and decreasing the incidence of postoperative nausea and vomiting (PONV). One study identifies the potential risk of bleeding during bariatric surgery, though there was no difference in terms of transfusion. So, *Ketorolac administered perioperatively has a role as a part of the foundational (WHO Step I) analgesic, but further studies of dose, safety and side effects specific to morbid obesity are needed (Grade C) [6]*.

Intermediate Analgesics: Tramadol and Tapentadol

Tramadol and Tapentadol are both intermediate-potency (WHO Step II) analgesics that may benefit surgical patients due to their multimodal mechanisms of action. Tramadol may be particularly useful when combined with acetaminophen. The use of tapentadol has not been yet reported specifically in this patient population. The current recommendation consider that *Tramadol may be appropriate intermediate or Step II analgesic for postoperative pain in patients with morbid obesity (Grade B) [6]*.

Opioids Analgesics

To achieve satisfactory pain control in obese patients after surgery, use of opioids is often inevitable. Through the review of the literature base on the evidence available for the management of acute pain on morbid obesity, the current recommendations conclude that the use of opioid PCA should be limited to patients with moderate to severe postoperative pain, probably when oral opioid therapy is not possible. Basal or continuous opioid infusions in patients with morbid obesity and particularly those with undiagnosed or untreated OSA should be avoided. Patients with suspected sleep disordered breathing must be observed with overnight monitoring of respiratory adequacy, during the entire time PCA is used (*Grade C*) [6].

Adjuvants Analgesics

- *Pregabalin/Gabapentin*: Both of them plays an increasing role as a component of multimodal analgesia in non obese patients. In morbidly obese patients, single preoperative administration of 150 mg pregabalin resulted in improved analgesia, was opioid-sparing and reduced adverse effects such as nausea and vomiting [5]. Similarly, preoperative administration of 100 mg of gabapentin also produced significantly lower pain scores in recovery with less nausea-vomiting compared with placebo. However, pregabalin and gabapentin may be associated with increased sedation and postoperative respiratory depression. Current recommendations consider that *pregabalin and gabapentin may be useful adjuvants to opioids in*

postoperative pain control (Grade C) [6]. There is no consensus for dose, frequency or duration treatment. Their use in the perioperative period requires careful assessment of the risk-benefit in patients with morbidly obese and/or OSA.

- *Ketamine (NMDA antagonist) is increasingly used as an analgesic adjunct in the postoperative settings. Low doses of ketamine used in morbidly obese lead to a significant reduced opioid consumption and reduced need for rescue analgesia importantly. Limiting factors for ketamine are co-existing severe arterial hypertension and cardiac failure, although the induction of hypertension by low-dose ketamine is unlikely. For this reasons, low dose (0,1-0,5 mg/kg) ketamine as a single bolus or infusion has a potential role as a safe adjuvant analgesic (Grade C) [6].*
- *Dexmedetomidine is an α 2 receptor agonist with sedative and analgesic sparing properties. Various studies in morbidly obese population have shown that dexmedetomidine infusion perioperatively is safe and may help to minimize narcotic requirements, length of stay after laparoscopic bariatric procedures and decrease antiemetic use and the risk of developing PONV [11, 12]. When clonidine is used as a premedication, it has found to be more sedating and associated with bradycardia and hypotension. Dexmedetomidine infusion can be used to reduce opioid consumption and decreases PONV (Grade B) [6].*
- *Lidocaine. Intraoperative intravenous lidocaine has previously been shown to have a significant effect on improving postoperative pain control, especially in abdominal surgery. Very little information is available in patients with morbid obesity indicating a significant decrease in opioid consumption in PACU and at 24 hours post analgesia regimen. According to the previous considerations, systemic lidocaine may reduce analgesic consumption and improve postoperative pain (Grade B), but few studies are available and optimal dosing schedule in patients with morbid obesity is yet to be determined.*
- *Sugammadex. It has been shown that sugammadex allows a faster neuromuscular recovery after rocuronium muscle relaxation and prevents postoperative residual curarization. In a recent study comparing sugammadex with the administration with neostigmina, sugammadex is associated with less pain felt in the PACU. This “opioid-sparing” effect, combined with less PONV allows a faster discharge from the PACU. There is not enough evidence to make a recommendation about it, needing to carry out more studies for this purpose [13].*

Regional Techniques

TAP blocks: Transversus abdominis plane (TAP) block has been studied as a potential technique to aid with pain management in bariatric surgery. It has been shown to reduce morphine use and PONV in abdominal surgery. Other studies have found limited or no statistically significant difference in outcomes with this block. One potential explanation may be that, there is no significant added benefit of TAP block if local anesthetic is also infiltrated at trocar insertion sites. Like all regional techniques, the efficacy of TAP block is also operator dependent, and in patients with morbidly obesity the performance of TAP blocks may be more difficult. Current recommendations consider that, *TAP blocks may be of some*

benefit in patients with morbid obesity undergoing certain types of abdominal surgery, especially laparoscopic procedures (Grade C) [6].

Intraperitoneal and wound modalities: Continuous administration of local anesthetic has been reported at wound and/or intraperitoneal infusions.

Some studies that examines the use of continuous bupivacaine wound infusion in laparoscopic weight loss surgery (WLS) lasting up to 96 hours. There was a statistically significant decrease in opioid consumption, but this benefit was not sustained beyond the infusion and there was no improvement in patient pain scores.

On the other hand, intraperitoneal bupivacaine infusions have found a statistically improvement in pain scores and total opioid consumption. Likewise, the use of a one-time spray of bupivacaine applied at the esophageal hiatus once the pneumoperitoneum is established, resulted in statistically significant decreased in analgesic consumption, including shoulder tip pain. For this reasons, *these loco-regional analgesic modalities contribute to optimizing pain in open abdominal and laparoscopic surgical procedures (Grade C)*. Further investigations, standardization and technique refinement are required [6].

Neuroaxial techniques. Neuroaxial techniques for pain management have been shown in numerous studies to be highly efficient in reducing opioid-related complications. Continuation of regional anesthesia techniques into the postoperative period to provide analgesia is regarded particularly useful in obese patients undergoing open bariatric surgery. Neuroaxial techniques in morbid obesity have been primarily studied in the context of obstetric anesthesia; only a few studies are available in non-obstetric patients with morbid obesity. Epidural analgesia in patients submit to open bariatric surgery resulted in better pain scores, patient satisfaction, early recovery and ambulation. Then, *epidural analgesia improves pain and control and promotes earlier ambulation in patients with morbid obesity undergoing non-obstetrical non-laparoscopic abdominal procedures (Grade B) [6].*

Multimodal Analgesia

In addition to the techniques that have been highlighted above, there are studies which have examined multimodal analgesia by combining several of these modalities to optimize pain control, whether in combination or without the use of opioids. The classic multimodal approach includes the use of foundational analgesics and preincision wound infiltration with or without opioid PCA. This resulted in statistically significant lower postoperative opioid use, less sedation and higher patient satisfaction in PACU. *A multimodal pain management strategy for post-surgical acute pain optimizes pain control and reduces opioid consumption (Grade B) [6].*

CONCLUSION

Despite the increasing incidence of obesity in our society and the resulting demand for bariatric surgery, there is little evidence to guide the management of postoperative pain in these patients. Although intuitively, obesity seems to be a major risk factor for respiratory complications after surgery, the evidence does not support this notion as long as it is not

accompanied by OSA. The overall consensus subscribes the concept of multimodal analgesia by the use of opioid-sparing analgesic strategies, including local anesthetics, nonsteroidal antiinflammatory medications and possibly adjuvants to reduce the risk of opioid-induced respiratory complications.
